Geological Society, June 23.—Prof. J. W. Judd, F.R.S., President, in the chair.—The President announced that he had received from Prof. Barrois an intimation that the Geological Society of France would hold a special country meeting in the district of Finistère from the 19th to the 28th of August next, during which a variety of interesting excursions would be made under the guidance of MM. Barrois, Davy, and Lebesconte. Prof. Barrois, in writing, expressed the pleasure which it would give the members of the Geological Society of France if they were joined by some of their English *confrères*, but at the same time stated that as the accommodation for travellers was limited in the district, he would be glad to have timely notice from any one intending to take part in the meeting. Particulars were to be obtained from the Assistant Secretary, who would also communicate with Prof. Barrois.—The following communications were read:—On some perched blocks and associated phenomena, by Prof. T. McKenny Hughes, M.A., F.G.S. The author described certain groups of boulders which occurred on pedestals of limestone rising from 3 to 18 inches above the level of the surrounding rock. The surfaces of these pedestals were striated in the direction of the main ice-flow of the district, while the surrounding lower rock in no case bore traces of glaciation, but showed what is known as a weathered surface. He inferred that the pedestals were portions of the rock protected by the overhanging boulder from the down-pouring rain, which had removed the surrounding exposed parts of the surface. When the pedestals attained a certain height relatively to the surrounding rock the rain would beat in under the boulder, and thus there was a natural limit to their possible height. He referred to the action of vegetation in assisting the decomposition of the limestone, and considered that there were so many causes of different rates of waste and so many sources of error, that he distrusted any numerical estimate of the time during which the surrounding limestone had been exposed to denudation. Considering the mode of transport of the boulders, he thought that they could not have been carried by marine currents and coast-ice, as they had all travelled, in the direction of the furrows on the rock below them, from the parent rock on the north. Moreover, marine currents would have destroyed the glaciation of the rock and filled the hollows with debris. Furthermore, the boulders and striæ are found in the same dis-

trict at such very different levels and in such positions as to preclude the possibility of their being due to icebergs. Nor could the boulders represent the remainder of a mass of drift which had been removed by denudation, for the following reasons: (1) they were all composed of one rock, and that invariably a rock to be found in place close by; (2) any denudation which could have removed the clay and smaller stones of the drift would have obliterated the traces of glaciation on the surface of the rock; (3) the boulder which had protected the fine glacial markings below it from the action of the rains would certainly in some cases have preserved a portion of the stiff boulder-clay; (4) the margin of the boulder-clay along the flanks of Ingleborough was generally marked by lines of swallow-holes, into which the water ran off the boulder-clay; and when the impervious beds overlying the limestone had been cut back by denudation, a number of lines of swallow-holes marked the successive stages in the process; but there was not such evidence of the former extension of the drift up to the Norber boulders; (5) the boulders themselves were not rounded and glaciated in the same way as the masses of the same rock in the drift, but resembled the pieces now seen broken out by weathering along the outcrop of the rock close by. Having thus shown the improbability of these boulders having been let down out of a mass of drift the finer part of which had been removed by denudation, or of their having been masses floated to their present position on shore-ice, he offered an explanation of their peculiar position, which he thought was not inconsistent with the view that they belong to some part of the age of land-ice. That they were to be referred to some exceptional local circumstances seemed clear from the rarity of such glaciated pedestals, while boulders and other traces of glaciation were universal over that part of the country. He therefore pointed out, in explanation, that they occurred always where there was a great obstacle in the path of the ice: at Cunswick the mass of Kendal Fell curving round at the south and across the path of the ice; at Farleton the great limestone escarpment rising abruptly from Crooklands; at Norber the constriction of the Crummack valley near Wharfe, and the great mass of Austwich grit running obliquely across its mouth. In all these cases the ice had to force its way up hill; and there would be a time when it would just surmount the obstacle after a season of greater snowfall, and fall back after warm seasons, until it fell back altogether from that part. During the season of recession, boulders would be detached below the ice-foot; during the seasons of advance they would be pushed forward; and in those exceptional localities of isolated hills from which the drainage from higher ground was cut off, the boulders were left on a clean furrowed surface of limestone, which was then acted upon by rainwater and the vegetation, except where protected by the boulders. The author said that the reason why he objected to any numerical estimate of the time which had elapsed since the boulders were left on the glaciated surface was that we did know that the rate of weathering in the limestone was most unequal. He gave cases from Devonshire and the Lake District of extensive weathering in a few years. He had called attention to the great acceleration of decomposition where the vegetation encroached on the limestone, and he maintained that we had no constant measure to apply.—On some derived fragments in the Longmynd and newer Archæan rocks of Shropshire, by Dr. Charles Callaway, F.G.S. Further evidence was added to that given in the author's previous paper (*Q.J.G.S.*, 1879, p. 661) to show that the Longmynd rocks of Shropshire were chiefly composed of materials derived from the Uriconian series, and that the Uriconian series itself (Newer Archæan) was partly formed from the waste of pre-existing rocks. This evidence consisted of (1) the presence, throughout the greatly developed Longmynd conglomerates and grits, of purple rhyolite fragments, recognised by microscopical characters as identical with the Uriconian rhyolites of the Wrekin, and the occurrence of grains, probably derived from the same rhyolites, in the typical green slates of the Longmynd; and (2) the existence of conglomerate beds containing rounded fragments of granitoid rock in the core of the Wrekin itself, whilst the Uriconian beds of other localities, and especially those of Charlton Hill, contained waterworn pebbles, chiefly metamorphic. These pebbles appeared to have been derived from metamorphic rocks of three distinct types. The views put forward were founded on microscopical evidence, of which some details were given in the paper, and were supported by the views of Prof. Bonney, who had furnished notes on the microscopical characters of the rocks.—Notes on the relations of the Lincolnshire carstone, by Mr. A. Strahan, M.A., F.G.S. The Lincolnshire carstone has hitherto been supposed to be correlative with the upper part of the Speeton series, and to be quite unconformably overlain by the red chalk (*Quart. Journ. Geol. Soc.*, vol. xxvi. pp. 326–47). But the overlap of the carstone by the red chalk, which seemed to favour this view, is due to the northerly attenuation, which is shared by nearly all the Secondary rocks of Lincolnshire. Moreover, the carstone rests on different members of the Tealby group, and presents a strong contrast to them in lithological character, and in being, except for the derived fauna, entirely unfossiliferous. It is composed of such materials as would result from the "washing" of the Tealby beds. In general it is a reddish-brown grit, made up of small quartz-grains, flakes and spherical grains of iron-oxide, with rolled phosphatic nodules. Towards the south, where it is thick, the nodules are small and sporadic. Northwards, as the carstone loses in thickness, they increase in size and abundance, so as to form a "coprolite-bed," and have yielded specimens of *Ammonites speetonensis*, *A. plicomphalus*, *Lucina*, &c. When the carstone finally thins out, the conglomeratic character invades the red chalk, similar nodules being then found in this rock. The presence of these nodules, with Neocomian species, taken in connection with the character of the materials of the carstone, points to considerable erosion of the Tealby beds. On the other hand, there is a passage from the carstone up into the red chalk. It would seem, then, that the carstone should be regarded as a "basement-bed" of the Upper Cretaceous rocks. The Lincolnshire carstone is probably equivalent to the whole of the Hunstanton Neocomian, the impersistent clay of the latter being a very improbable representative of the Tealby clay. It therefore follows that the whole Speeton series is absent in Norfolk, and also in Bedfordshire. The unconformity at the base of the carstone becomes greater southwards, and the nodules have been derived from older rocks. Similarly north of Lincolnshire, where the Speeton series is overlapped, the nodules in the red chalk, marking the horizon of the carstone, have been derived from oolitic rocks. In the south of England it would seem that equivalents of the Speeton series reappear. The Atherfield clay contains an indigenous Upper Speeton fauna, while a pebble-bed near the base of the Folkestone beds is described by Mr. Meyer as containing derived oolitic pebbles, and being probably the representative of the Upware deposit, and presumably, therefore, also of the Lincolnshire carstone.—The geology of Cape Breton Island, Nova Scotia, by Edwin Gilpin, Jun., F.R.S.C., Inspector H.M. Mines. After referring to previously published descriptions of Cape Breton geology, the author stated that the various formations found in the island had been thus classified by the officers of the Geological Survey:—

Pre-Cambrian (Laurentian)
including { The Felsite series. / The Crystalline Limestone series.
Lower Silurian.
Devonian.
Carboniferous, including
- Lower Coal-formation.
- { Gypsiferous series. / Limestones, &c.
- Millstone-Grit.
- Middle Coal-formation.

He then proceeded to give an account of each system and its subdivisions in order, commencing with the most ancient, and adding a few detailed sections of the rocks belonging to some of the principal series. He described the distribution and relations of the several divisions. The paper concluded with a few notes on the superficial geology of the island. There is a general absence of moraines and of the fossiliferous Post-Pliocene marine clays of the Lower St. Lawrence. The older beds are generally exposed, but deeper soils and deposits with erratic boulders are found overlying the Carboniferous beds. Marks of recent ice-action are found on the shores of some of the lakes, and are due to the ice being driven by the wind.—On the Decapod Crustaceans of the Oxford Clay, by James Carter, F.G.S. The author commented on the paucity of these fossils as indicated in British lists, only three or four species having hitherto been recorded. The discovery of considerable numbers of Decapod Crustaceans in the Oxford Clay of St. Ives has enabled the author to increase the list materially. Many have been collected by Mr. George,

of Northampton. These fossils occur in the clay immediately beneath the St. Ives rock, and therefore presumably in the uppermost zone of the Oxford Clay. Many of the specimens are more or less mutilated, but some fifteen or sixteen distinct species have been made out. None of these have been recorded as British except *Eryma Babeaui*, mentioned by Mr. Etheridge as having been found in the Kimmeridge Clay. Seven species are identified as foreign forms, and seven are new to science. They are distributed as follows :—

Eryon	1	species.
Eryma	5 or 6	,,
Glyphea	2	,,
Magila	2 or 3	,,
Mecochirus	2	,,
Goniochorus	1	,,
Undetermined	3	,,

Nearly all the forms being to the type of the Macrura, the Brachyura being doubtfully, if at all, represented.—Some well-sections in Middlesex, by W. Whitaker, B.A. Lond., F.G.S. Accounts of many well-sections and borings having been received since the publication of vol. vi. of the Geological Survey *Memoirs*, the author now gave more or less detailed descriptions of fifty-six of these, all in the Metropolitan county, and all either unfinished or, in a few cases, with further information as to published sections. The depths range from 59 to 700 feet, more than half being 300 feet or more deep. Nearly all pass through the Tertiary beds into the Chalk, and most have been carried some way into the latter. Papers descriptive of like sections in Essex, Herts, and Surrey have been sent to Societies in those counties. —On some Cupriferous Shales in the Province of Houpeh, China, by H. M. Becher, F.G.S. This communication contained some geological observations made during a visit to a locality on the Yangtse River, near I-chang, about 1000 miles from the sea, for the purpose of examining a spot whence copper ore (impure oxide with some carbonate and sulphide) had been procured. The principal formations in the neighbourhood of I-chang were said to be Palæozoic (probably Carboniferous) limestones of great thickness, overlain by brecciated calcareous conglomerate and reddish sandstones, which form low hills in the immediate vicinity of the city. About fifty miles further west the limestones pass under a great shale-series with beds of coal, the relations of which to the sandstones are not clearly ascertained. The copper ore examined by the writer came from the sbales, which contained films and specks of malachite and chrysocolla, and in places a siliceous band containing cuprite, besides the oxidised minerals, was interstratified in the beds. Occasionally larger masses of pure copper ore are found embedded in the strata. The ground had not been sufficiently explored for the value of the deposits to be ascertained.—The Cascade Anthracite Coal-field of the Rocky Mountains, Canada, by W. Hamilton Merritt, F.G.S. The coal-field named occurs in the most eastern valley of the Rocky Mountains, that of the Bow River, and, like other coal-fields of the country, consists of Cretaceous rocks, which lie in a synclinal trough at an elevation of about 4300 feet above the sea. The underlying beds, of Lower Carboniferous, or possibly Devonian, age, rise into ranges 3000 feet higher. Further to the eastward the Jurassic and Cretaceous coal contains a large percentage of hygroscopic water and volatile combustible matter, and has the mineral composition of lignite. The average composition is :—

	Per cent.
Fixed carbon...	42
Volatile combustible matter ...	34
Hygroscopic water	16
Ash	8
	100

As the mountains are approached, the amount of hygroscopic water is found to diminish by about 1 per cent. for every 10 miles, and 15 miles from the range the percentage is about 5. In the foot-hills the lignites pass into a true coal, with 1·63 to 6·12 per cent. of hygroscopic water, and 50 to 63 per cent. of fixed carbon. In the Cascade River coal-field the average character of the coal is that of a semi-anthracite, with the following composition ;—

	Per cent.
Fixed carbon	80·93
Volatile combustible matter ...	10·79
Hygroscopic water	71
Ash	7·57
	100·00

The coal-seams have been subjected to great pressure, and the change in the quality of the coal appears to be due to metamorphic influence.—On a new Emydine Chelonian from the Pliocene of India, by Mr. R. Lydekker, B.A., F.G.S. The author described the shell of an Emydine tortoise from the Siwaliks of Perim Island, Gulf of Cambay, which he regarded as decidedly distinct from any of the previously described Siwalik species, and proposed to refer to the genus *Clemmys*, with the name of *C. watsoni*, in compliment to the donor of the specimen.—On certain Eocene formations of Western Servia, by Dr. A. B. Griffiths, F.R.S.E., F.C.S. Communicated by the President. A great thickness of paper-shales containing paraffin occurs near the River Golabara ; these extend over 30 square miles of country. Small beds of clay with rock-salt are also found : the whole is said to resemble the paraffin and salt districts of Galicia. The paraffin shale is free from bituminous impurities. It contains :—

	Per cent.
Paraffin wax	1·75
Water of combination	3·02
Ammonia	1·18

The mineral constituents of the shale are :—

	Per cent.
Alumina	32·86
Iron oxide...	5·20
Magnesia	1·26
Lime	1·21
Potash	2·17
Soda	0·41
Silica	56·85
Loss	0·04
	100·00

The brown coal of the neighbourhood, whose natural distillation has most probably yielded the hydrocarbon in the shales, contains :—

	Per cent.
Carbon	49·2
Hydrogen	1·1
Water, combined	30·2
Water, hygroscopic	19·5
	100·00

The beds containing these coals have been invaded by eruptive porphyry and trachytic rocks, of which the former contains 75½ and the latter 61 per cent. of silica. The clays from which the shales were originally formed contain abundance of marine Diatomaceæ and Foraminifera (chiefly Nummulites), as also species of *Ostrea*, *Cyrena*, *Cerithium*, *Voluta*, and *Nautilus*, together with the remains of Placoid and Teleostean fishes.

Paris

Academy of Sciences, July 5.—M. Jurien de la Gravière, President, in the chair.—Memoir on the life and works of Louis-François-Clement Bréguet, Member of the Academy of Sciences, born at Paris on December 22, 1804, died October 27, 1883, by M. de Jonquières.—Obituary notice of M. H. Abich, Corresponding Member of the Section for Mineralogy, who died at Vienna on July 1, 1886, by M. Daubrée.—Preliminary note on the principles and method employed in a study on the movement of the hydro-extractor, about to be presented to the Academy, by M. de Jonquières.—Experiments on a new apparent paradox in hydraulics, by M. A. de Caligny.—Final objections to M. de Bussy's formulas on the roll of vessels, by M. A. Ledieu. It is pointed out that M. de Bussy's theorising is of a purely speculative character, of very little practical

utility. After the protracted studies of Froude and Rankine in England, published in the *Transactions* of the Institution of Naval Architects (1861–64), and of MM. Bertin and Bénazé in France, the subject may be regarded as exhausted.—On the real position to be assigned to the fossil flora of Aix, in Provence, by M. G. de Saporta. It is argued against the views of M. Fontannes on stratigraphic grounds that the whole series of varied and numerous deposits giving birth to the flora of Aix, cannot be reduced to the gypsum alone, or to the section of this gypsum contiguous to the beds at Cyrènes. In a further paper it will be shown that the palæontological indications are equally opposed to M. Fontanne's opinion.—Note and photographs of the thunderstorm of May 12, 1886: spiral form of lightning, by M. Ch. Moussette. The photographs taken at Auteuil on this occasion seem to indicate a general law that the electrical discharges between the clouds and the earth assume the normal form of irregular spirals.—Observations of the new planet 259 made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—On the development in series of the potential of a homogeneous revolving body, by M. O. Callandreau. In this paper the author verifies the two formulas of Legendre and Laplace relative to the exterior and interior points of a spheroid usually defined by the equation $r = a(1 + \alpha y)$.—Memoir on the rowing-vessels of antiquity, by M. Corazzini. The author attempts to solve the difficult problems associated with the construction of the *naves longæ*, and reconstructs the Roman polyremes in a manner which seems to harmonise best with the monuments and the descriptions of classic writers.—On the refraction of carbonic acid and of cyanogen, by MM. J. Chappuis and Ch. Rivière. The results of the authors' researches on the refraction of carbonic acid at 21° and up to 19 atm. are resumed in the formula—

$$n - 1 = 0{\cdot}000540p(1 + 0{\cdot}0076p + 0{\cdot}0000050p^2),$$

in which n denotes the index for the ray D, and p the pressure in metres of mercury. The refraction of cyanogen has also been studied at different temperatures between the pressures of 1m. and 2m. or 3m. of mercury, the series of experiments relative to a determined temperature being resumed in a formula of the form $n - 1 = ap(1 + bp)$.—On the electrical conductivity of the mixtures of neutral salts, by M. E. Bouty.—On the decomposition of the perchloride of iron by water, by M. G. Foussereau. The author had already employed the measure of electric resistance to determine the nature and proportion of foreign substances contained in water and alcohol, and the conditions under which these fluids acquire the greatest degree of purity. He now applies the same method to the study of the progressive alterations of fluids, and especially of saline solutions under the influence of the dissolvent. The present paper deals specially with the perchloride of iron.—Note on a transmitting dynamometer with a system of optical measurement, by M. P. Curie. This apparatus consists of a horizontal arbor supported by two bearings. Two pulleys at the extremities of the arbor serve to transmit the motion from the motor to the receiver, and the work done is measured during the motion by the torsion of the arbor between the two pulleys.—Temperature of the deep waters in the Lake of Geneva, by M. F. A. Forel. Observations taken during the years 1879–86 show that at great depths the temperature never falls below 4°, and varies normally between 4°·6 and 5°·6. From his experiments the author also infers that the heat penetrates to the lower layers mainly through the mechanical intermingling of the upper with the deep waters under the action of the winds. The same explanation, he argues, should be applicable to all lakes and to all seas confined by bars, notably the Mediterranean, whose deep waters have a mean temperature of 13°.—Absorption spectra of the alkaline chromates and of chromic acid, by M. P. Sabatier.—On the heat of transformation for vitreous selenium to metallic selenium, by M. Ch. Fabre. Vitreous is transformed to metallic selenium by heating it to 96° or 97°, the transformation being accompanied by a considerable development of heat, which is here directly determined by means of M. Berthelot's calorimeter.—Action of vanadic acid on the alkaline haloid salts, by M. A. Ditte.—On the fluorides of the metalloids, by M. Guntz. By practical tests the author has verified his hypothesis that the fluoride of lead is decomposable by all the chlorides of the metalloids. With the oxychloride of phosphorus the reaction is so regular that it gives a convenient process for preparing the oxyfluoride of phosphorus.—On the hydrate of baryta, BaO,H_2O_2, by M. de Forcrand.—A contribution to the study of the alkaloids, by M. Œchsner de Coninck.—Isomery of the camphols and of the camphors, by M. Alb. Haller.—Researches on the chemical composition of the grease of sheep's wool, by M. A. Buisine. The grease of Australian wool yielded for 100 of dry residuum 7·1 of acetic acid, 4 of propionic acid, 2·6 of benzoic acid, 2·59 of lactic acid, 1 of capric acid.—Acidimetric analysis of sulphurous acid, by M. Ch. Blarez.—Researches on the development of beetroot; study of the leaf, by M. Aimé Girard.—Comparative studies on the influence of the two orders of vaso-motor nerves, on the circulation of the lymph, on their mode of action, and on the mechanism of lymphatic production, by M. S. Lewachew.—On a process of indirect division by threes of the cellules in tumours, by M. V. Cornil.—The house-bug and the seat of its fetid secretion: the dorsal abdominal glands of the larva and nymph; the sternal thoracic glands of the adult, by M. J. Künckel.—On the influence of certain Rhizocephalous parasites on the exterior sexual characters of their host, by M. A. Giard.—On the circulatory system of the Echinidæ, by M. R. Kœhler.—On the seeds of Bonduc, and their active principle as a febrifuge, by MM. Ed. Heckel and Fr. Schlagdenhauffen. These seeds are supplied by two closely allied exotics: *Guilandina Bonducella, L.* (*Cæsalpinia Bonducella*, Flem.) and *Cæsalpinia Bonduc*, Roxb. Their therapeutic properties are shown to reside in the bitter principle, which acts against intermittent fevers as efficaciously as the salts of quinine.—On the Triassic system of the Eastern Pyrenees, in connection with M. Jacquot's recent communication, by M. A. F. Nogués.—Invertebrate fauna of the Mentone grottoes, Italy, by M. Emile Rivière. In these caves the author has discovered 171 species of invertebrates, comprising 20 fossil, 125 living marine, and 26 land species. Amongst the living marine species 50 are at once Mediterranean and oceanic, 62 exclusively Mediterranean, and 6 oceanic.

HAND-BOOK OF PLANT DISSECTION

Hand-Book of Plant Dissection. By J. C. Arthur, M.Sc., Charles R. Barnes, M.A., and John M. Coulter, Ph.D. (New York: Henry Holt and Co., 1886.)

THIS work will take the same place in the botanical teaching of the United States as will be occupied in this country by the "Practical Botany" of Messrs. Bower and Vines, when the latter is completed. Both are essentially guides to the laboratory instruction which now forms the most important part of every efficient course of botany.

The American hand-book differs from its English prototype in two important respects: first, in the fact that it begins with the lowest plants, while the English work begins with the highest; and secondly, in its more rigid adherence to the type system. Prof. Bower did not limit the work entirely to the main types, but frequently introduced other plants, which happened to be more favourable for the study of particular points of structure. The authors of "Plant Dissection," on the other hand, give us the type, and the type only. Their plan has the advantage of simplicity, but several points have to be passed lightly over which could have been studied efficiently in plants other than the selected types. On the whole, the more elastic method of the "Practical Botany" seems to us to be more satisfactory. Any teacher of botany would select Cucurbita for the study of the sieve-tubes, Caltha, or some allied plant, for the embryo-sac, and so on; and yet these are not plants which would be well suited for generally typical examples.

As regards the other point, whether it is better to begin at the upper or lower end of the vegetable kingdom, it may perhaps be said that the former is the course better adapted for beginners, while the latter has its advantages in the case of advanced students. If the learner has no previous knowledge of plants at all, it may be difficult to rouse his interest in such obscure forms as Oscillaria or Cystopus, while the study of some familiar plant, such as the sunflower or shepherd's purse, is much more likely to attract him. On the other hand, if some preliminary knowledge may be assumed, there will be no objection to following the strictly logical course of proceeding from the simpler to the more complex.

The "Hand-Book of Plant Dissection" begins with a short introduction on reagents, section-cutting, &c., and then come the types, occupying the bulk of the work. They are twelve in number, and have been selected as follows:—For the lower Chlorophyceæ, *Protococcus viridis;* for the Cyanophyceæ, *Oscillaria tenuis;* for the Conjugatæ, *Spirogyra quinina;* for the Phycomycetes, *Cystopus candidus;* for the Ascomycetes, *Microsphæra Friessi;* for the Liverworts, *Marchantia polymorpha;* for the Mosses, *Atrichum undulatum;* for the Ferns, *Adiantum pedatum;* for the Gymnosperms, *Pinus sylvestris;* for the Monocotyledons, *Avena sativa* and *Trillium recurvatum;* and lastly, for the Dicotyledons, *Capsella Bursa-pastoris.* It will be seen that while one or two of these plants are strictly American forms, most of the types are cosmopolitan.

It would be easy to criticise the selection in some of the cases: thus, "Protococcus" is not really entitled to the first place on the list, for its cells are more highly organised than those of the Oscillaria. Pythium shows the sexual organs much better than Cystopus, and Microsphæra is perhaps not so characteristic an Ascomycete as might have been found. On the whole, however, the types are good ones.

A few points may be mentioned where there appears to us to be room for serious criticism. It is evident from the remarks on p. 55 that Sachs's old classification of the Thallophytes is adhered to. Surely after the publication of De Bary's papers in the *Botanische Zeitung*, in 1881, and of Goebel's "Grundzüge der Systematik," in 1882, there is no excuse for retaining this manifestly artificial arrangement. Sachs's grouping of the Thallophytes by their sexual organs alone, without any regard to general structure, has been unkindly, but pointedly, compared to the sexual system of Linnæus, which is not usually reckoned as a natural arrangement. How inexpedient the classification in question is for the student is well shown in the work before us on the page referred to, where the reader is advised to study Nemalion or Batrachospermum in order to understand the fruit of Microsphæra. Can any one seriously believe that detailed homologies can be traced between so isolated a group as the red seaweeds and a highly specialised parasitic member of the Ascomycetous Fungi?

Going on to the chapter on the Liverwort, the footnote on p. 75 seems likely to confuse rather than to enlighten the student. The archegonia are *not* called sporogonia after fertilisation by any one who wishes to keep the distinction between the sexual and asexual generations clear in the mind of the learner. The sporogonium arises from the oosphere only; the archegonium, as distinguished from the oosphere, takes no part in its formation.

In the same chapter a statement on p. 82 that "the antheridia are modified hairs" demands notice. This is a bad example of old-fashioned morphology. The antheridia of the Liverworts are modified successors of the antheridia of the lower plants. The ancestors of highly organised plants like Marchantia must have long possessed sexual organs, probably at least as long as they have possessed "trichomes." The same mistake reappears on p. 120 in the description of the fern, when the "trichomes" are said to appear "in the form of sporangia." Either this is merely a roundabout way of stating that the sporangia are of epidermal origin, or else it means that these reproductive organs are actually due to the modification of hairs. The latter view will hardly commend itself to any one who realises that the spores of the fern are homologous with those of the Muscineæ.

A repetition of the same confusion of ideas on p. 125 need not be further noticed.

In the account of the anatomy of the leaf of Pinus there is an error as to a simple matter of fact which ought to be corrected. On p. 154, *d* and *e*, the thin-walled cells of the mesophyll, are said to be empty, while those with bordered pits are described as having "more or less conspicuous contents." This is just the reverse of the truth. The thin-walled cells have protoplasmic con-

tents throughout life, while the tracheides with bordered pits (transfusion tissue) contain, in the mature condition, nothing but water.

On p. 164 the statement that there is finally "free communication" between the contiguous tracheides of the wood of Pinus is erroneous. The pits are closed, at any rate as long as the wood serves its main function of conveying the sap.

At p. 171, in the same chapter, there is a repetition of Hofmeister's old mistake as to the deliquescence of the original cell-walls of the endosperm in the Conifers. Strasburger showed in his "Angiospermen und Gymnospermen," that this idea was due to Hofmeister having confused the disorganised cells of the nucellus with those of the endosperm. The Conifers have one and the same endosperm throughout the development of the ovule: there is no distinction of "primary and secondary" endosperm.

Judging from the footnote on p. 209, there seems to be some confusion between the xylem and the bundle-sheath in Trillium.

It is to be regretted that the student is not shown how to investigate the minute structure of the angiospermous embryo-sac when ready for fertilisation.

In spite of the rather serious faults noticed, the book on the whole is a good and useful one. D. H. S.

MR. MERRIFIELD'S "TREATISE ON NAUTICAL ASTRONOMY"

A Treatise on Nautical Astronomy for the Use of Students. By John Merrifield, LL.D., F.R.A.S. (London: Sampson Low, Marston, Searle, and Rivington, 1886.)

THIS is an excellent work for the student, evidently compiled with considerable care, which may also be consulted with advantage by the seaman. Of course the author does not claim originality, excepting in one particular, viz. a method of his own for "clearing the lunar distance," as, in point of fact, nearly everything the work contains has been published in previous treatises. Mr. Merrifield deserves, however, the credit of placing clearly before the student many points which are only touched on by other writers—notably the account of the correction for refraction, and the explanation of the fact that the maximum altitude is not invariably the meridian altitude, a point which is only touched on by a footnote in Raper, and is usually ignored entirely; yet which is of considerable importance in the case of the moon. The examples, also, which are given at the end of each chapter are of great use to the student, as from them a knowledge is obtained of the subjects he is likely to be examined in; and as these questions have been selected from many examination papers, they are an excellent guide. In the theoretical part of nautical astronomy the book is nearly all that can be desired, and this part can always be learnt better on shore than in a ship, where the constant noise and interruption, together with perpetual motion at sea, renders study all but impracticable: in one or two cases, however, Mr. Merrifield also touches on the practical use of instruments, &c., and on these subjects he is naturally not so good an authority. It may perhaps, therefore, be advisable to point out the usual course of proceedings in Her Majesty's surveying-vessels, both in correcting instruments and also in ascertaining positions at sea.

First, with regard to the sextant, the error of collimation is not readily obtained, as stars only are available, and there are no means of illuminating the wires in the telescope, so that a bright moonlight night is requisite. Secondly, with respect to the errors of centering and graduation, Mr. Merrifield suggests that the combined error should be ascertained by means of measuring the distance between several pairs of stars by the instruments, the correct distances having been previously calculated. But here the varying nature of the refraction prevents good results, and a better method is to measure the distances both by the sextant and by the repeating circle as in the latter instrument all errors are eliminated.

In the account of the artificial horizon Mr. Merrifield says that "it is used for taking altitudes when the sea horizon is obscured," being apparently under the impression that it can be used on board a vessel. Were such the case, it would often relieve the mind of many an anxious navigator, but, unfortunately, the constant motion of a ship altogether precludes its use at sea; it is true that the late Capt. Becher, R.N., invented a method of observing altitudes at sea, in foggy weather, by attaching a small pendulum, suspended in oil, outside the horizon-glass of a sextant; to this a horizontal arm was fastened which carried at its inner end a slip of metal showing the true horizon when seen in a certain position; but this did not prove a success, and is now almost forgotten; and there is nothing to trust to but the compass and log when the horizon is obscured. The true use of the artificial horizon is to obtain observations on shore, and the sea horizon should never be used then. The best artificial horizon is a trough filled with mercury, covered with a glass roof, but this cannot be used in the extreme cold of the Arctic regions, and consequently there a plate of dark glass is substituted, which is adjusted by spirit levels. The error of the artificial horizon is due to two causes, first the imperfections in the glass roof, which, as Mr. Merrifield remarks, may be guarded against by reversing the roof; and secondly, owing to the attraction of mountain masses causing the mercury to depart from the true level. Could some means be found which would enable the seaman to take observations, in a vessel, independently of the sea horizon, it would be the most useful nautical discovery of the age, but this is not to be effected, as Mr. Merrifield suggests, by mounting the artificial horizon on gimbals, for even if the ship were in herself rigid, the motion at sea would preclude the possibility of obtaining observations, as the position of the observers could not be changed with sufficient rapidity to suit the ever-varying angle of reflection from the horizon, with respect to the observer on the deck; and Mr. Merrifield's own experiences of the difficulties of obtaining observations from the roof of a quiet house must have taught him that it would be much more difficult in a vessel which is constantly vibrating from the motion of the engines or other disturbing causes. The idea of placing a piece of glass on the mercury to still its vibrations, was some years ago promulgated by the late Staff-Commander George, attached to the Geographical Society, who invented a very useful little artificial horizon

for the benefit of travellers, in which the floating glass was part of the plan.

In obtaining the position of a ship at sea the difficulty is to get observations both for latitude and longitude at the same time, as all other observations depend on the distance covered by the vessel in the time which has elapsed between the observations. Now, as this distance depends not only on the direction and rate of the vessel through the water, but also on the direction and rate at which the water itself is moving, and as this latter element in the calculations cannot be ascertained with precision, it follows that all observations at sea which depend on the ship's run in the interval have an element of uncertainty. The best time to obtain simultaneous observations for latitude and longitude is at twilight, morning and evening, as then the horizon is clear, and, unless the weather is very cloudy, some stars can be seen. Here Sumner's method is invaluable, as three or more stars can be utilised and the correctness of the result guaranteed, provided, of course, that the chronometer is correct. In the day-time the only chance to obtain simultaneous observations is when the sun and moon are both visible, or when Jupiter, or Venus, happen to pass the meridian at an interval of over $2\frac{1}{2}$ hours from noon, as then, in bright weather, their meridian altitudes can be obtained by a practised observer with a good sextant.

One of the difficulties in obtaining good results at sea is owing to the varying nature of the refraction, more especially close to the horizon. This may be guarded against in the case of the meridian altitude of the sun by observing, when practicable, its altitude with the north and south horizons. To show the closeness of the results ascertained in this manner, it is only necessary to observe that H.M.S. *Triton*, when fixing the position of the Ower and Lemon light-vessel on the east coast of England in 1884, obtained the latitude on four different days, the results being as follows :—

June 25	...	...	...	Lat. $53^{\circ}\ 7'\ 56''$ N.
July 9	...	...	...	,, 53 8 0 N.
July 11	...	...	...	,, 53 7 54 N.
July 12	...	...	...	,, 53 7 57 N.

an extreme range of $6''$, or 600 feet, in the latitude. Such a close accordance shows the value of this method, which is recommended by Raper.

As regards obtaining the longitude by lunar distances, this has been gradually falling into desuetude owing to the quicker passages made by vessels and to the cheapness of chronometers. There can, however, be no doubt of its utility, as it is the only good way of obtaining the position of the ship at sea should any accident happen to the chronometers, and it is to be regretted that it is so seldom practised, particularly when we remember the excellent results obtained by the older navigators, especially by Cook. For the actual observation the repeating circle is a far better instrument than the sextant, as by it the distance between the sun and moon is observed with much greater accuracy, a matter of the utmost importance when we remember that an error of one minute in the distance makes an error of twenty-five miles of longitude under the most favourable circumstances. It is therefore evident that this observation requires to be made with the utmost care and that constant practice is necessary to obtain good results.

In the problem of obtaining the true bearing of a terrestrial object from a ship at sea, Mr. Merrifield has omitted the correction of the angular distance due to the height of the object : this is probably an accidental omission, but although it does not usually amount to much, it is desirable the student should be acquainted with it.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Laws of Solution

In my paper on "Chemical Affinity and Solution," published in NATURE, vol. xxxiii. p. 615, I gave some general proofs (taken from Thomsen's researches on thermo-chemistry) of the truth of my theory of solution. I shall now show that there are certain well-marked and definite laws of solution which are in complete accord with that theory, and seem to me to place it beyond doubt. In all chlorides, bromides, iodides, sulphates, and nitrates, for which data are available, the heats of solution in water *vary directly*—

(1) As the affinity (measured by heat of combination) of the positive element of the salt for O varies ;

(2) As the affinity (measured by heat of combination) of the negative element or radicle of the salt for H varies ;

And *inversely*—

As the affinity (measured as above) between the positive and negative elements of the salt varies.

The following examples will make this plain :—

Compound	Heat of combination	Difference	Heat of solution of chloride	Difference
[Mg,Cl_2	151010	—	35920	—
[Mg,O,Aq]	148960	2050	—	—
[Ca,Cl_2]	169820	—	17410	+ 18510
[Ca,O,Aq]	149260	20560	—	—
		− 18510	—	+ 18510
[Ca,Cl_2]	169820	—	17410	—
[Ca,O,Aq]	149260	20560	—	—
[Sr,Cl_2]	184550	—	11140	+ 6270
[Sr,O,Aq]	157780	26770	—	—
		− 6210	—	+ 6270
[$SrCl_2$]	184550	—	11140	—
[Sr,O,Aq]	157780	26770	—	—
[Ba,Cl_2]	194740	—	2070	+ 9070
[Ba,O,Aq]	158760	35980	—	—
		− 9210	—	+ 9070

Similar results are obtained if we substitute the alkali metals for above, but there is a variation in the case of metals which form insoluble oxides or hydrates. In the latter case the heats of solution are not so great as they should be if compared with above compounds. Among themselves, however, they follow the laws pretty closely, and seem arranged in groups. Thus, $ZnCl_2$ and $CdCl_2$, $FeCl_2$, $CoCl_2$, and $NiCl_2$ form two such groups.

The foregoing examples illustrate the effect of the change of the positive element of the salt on the heat of solution. Now let us change the negative element and we shall see the same result.

Compound	Heat of combination	Difference	Heat of solution	Difference
[K,Cl]	105610	—	−4440	—
[H,Cl,Aq]	39315	66295	—	—
[K,Br]	95310	—	−5080	+640
[H,Br,Aq]	28380	66930	—	—
		−635		+640
[K,Br]	95310	—	−5080	—
[H,Br,Aq]	28380	66930	—	—
[K,I]	80130	—	−5110	+30
[H,I,Aq]	13170	66960	—	—
		−30		+30

These relations obtain for the haloid salts of all the metals for which data were available for comparison. The only exception is $AuCl_3$ and $AuBr_3$, the difference of heats of solution of these salts being too great according to the foregoing laws. They are apparently proportional, however.

There is another way of showing these laws and also of showing the conditions which determine the absolute amount of heat of solution, whether positive or negative. If we take the sum of the heats of formation of any salt and of water on the one hand, and on the other, instead of measuring the heat of solution directly, take the sum of the heats of formation of the oxide, of the acid and of neutralisation, we shall find that the heat of solution is the difference of these sums—positive when the latter sum is the greater, and negative when it is the less. This exhibits in a striking manner the relations of the various affinities to solution, and is very suggestive when we consider that the heat of solution regularly increases with the heat of formation of [M,O,Aq], and when the heat of $[MO] > [M,Cl_2]$, decomposition of water takes place. Consider the following examples :—

Compound	Heat of combination	Compound	Heat of combination
[Mg,OAq]	148960	[Mg,Cl_2]	151010
[2H,Cl,Aq]	78630	[H_2O]	68360
Neutr.	27690		
	255280		219370
	219370		
Difference	35910 = Heat of solution.		
[Sr,O,Aq]	157780	[Sr,S,O_4]	330900
[H_2,S,O_4,Aq]	210770	[H_2,O]	68360
Neutr.	30710		
	399260		399260
	399260		
Difference	0 = Heat of solution. Salt insoluble.		
[K_2,O,Aq]	164560	[K_2,N_2O_6]	242970
[H_2,N_2,O_6,Aq]	102190	[H_2,O]	68360
Neutr.	27540		
	294290		311330
	311330		
Difference	− 17040 = Heat of solution.		

The above illustrate the cases of positive, negative, and zero heats of solution. These relations obtain with all salts, whether the oxide is soluble or not. The only discrepancy I found was in the case of silver chloride, which showed a slight negative heat of solution; but as its affinity for O is excessively small, it is not surprising it should be an abnormal case.

These laws of solution explain and are illustrated by many cases of constant differences in the heats of formation of similar compounds in water. Thus it has been pointed out in Muir and Wilson's "Thermo-Chemistry" that between the heats of formation of soluble chlorides, bromides, and iodides in water, there is a constant difference, no matter what the positive element is. For example, consider the following cases :—

Compound	Heat of formation	Compound	Heat of formation
[H,Cl,Aq]	39315	[H,Cl,Aq]	39315
[H,Br,Aq]	28380	[H,I,Aq]	13170
Difference	10935	Difference	26245
[K,Cl,Aq]	101170	[K,Cl,Aq]	101170
[K,Br,Aq]	90230	[K,I,Aq]	75040
Difference	10940	Difference	26130

Now the reason of this is perfectly obvious in the light of the laws of solution. Any variation from the above differences in the heat of formation of the undissolved salt is at once counterbalanced by the heat of solution, which varies inversely. Thus :—

Compound	Heat of formation	Heat of solution	Total
[H,Cl]	22000	17315	39315
[H,Br]	8440	19940	28380
Difference	13560	−2625	10935
[Na,Cl]	97690	−1180	96510
[Na,Br]	85770	−190	85580
Difference	11920	−990	10930

and so on in other cases.

WM. DURHAM

Ice on the Moon's Surface

IN May 1884 Mr. Peal, of Sibsagar, in Assam, who has studied the moon's surface with great attention, sent me a paper in which he maintained views closely resembling those of Capt. Ericsson (NATURE, p. 248) on the glacial origin of the lunar craters. In my answer I suggested that it was difficult to admit the existence of ice on the moon's surface, without a layer of water vapour over it, and that the telescope proves that if such vapour exists it is only in extraordinarily small quantities. It seems due to Mr. Peal, who was undoubtedly ignorant of Capt. Ericsson's paper of 1869, to draw attention to the correspondence. I am not sure whether the paper has been yet published.

Cambridge, July 17 G. H. DARWIN

Luminous Clouds

I AM not sure of the date, but believe it was in June 1885 that I called attention in your journal to a strange effect of bright silvery lighted clouds, which remained visible in the north-west sky after sunset until nearly 11 p.m. Several times this summer I have noted repetitions of these same curiously lighted cloud-forms, but have never seen such a wonderful display of this "after-sheen" as that of this evening, July 12.

The day from 11 a.m. until 6 p.m. had been wet, followed by a clear-up toward sundown, with a warm orange-coloured sunset near the horizon; above this, and extending nearly to the zenith, lay masses of brilliant and, one would almost say, self-illuminated cloud-ripples looking like an inverted sea of frosted silver or mother-of-pearl.

There was a strongly-marked focus in the light above the place of the sun, but it extended far beyond that both north and west. The vapour forming these cloud-waves, and which received this intense white light, must, I think, have been at a great elevation, for though all the lower vapour near the horizon retained its usual orange glow long after sunset, there was never any indication of colour upon these clouds from the beginning of the effect, about 7.30 p.m., until it disappeared soon after 10 p.m. The moon, which was in the southern part of the sky, looked quite warm in colour when contrasted with the almost bluish-white glare upon this vapour. ROBT. C. LESLIE

Moira Place, Southampton, July 12

THE luminous night clouds seen here on the 22nd ult. (NATURE, July 1, p. 192) have recurred, with a very remarkable development on the night of the 8th inst.

The sketches illustrate phases one hour apart from midnight to 2 a.m.; the last made solely by "cloud-light" in a window with northern aspect! The long luminous belt began to form at 11.30 p.m., fading out at 2.30 a.m. It extended obliquely from N. 10° W. to N. 30° E. in the wind's direction, which was light from N.W. Temperature subsequently fell.

Last night (9th inst.) the upper northern sky was obscured with cumulous cloud, but in a clear space above the horizon, from N. to N.E., a belt of cloud resembling that of the previous night extended obliquely. In this case the belt was dark; but beneath, and apparently descending from it, bright luminous patches formed of a golden lustre at midnight, and faded out at 1.30 a.m. Wind again from N.W., light. Temperature cool for season.

Examined with a good field-glass, these cloudlets present the usual cirrous type in all but singular luminosity, and little (if any) of the aurora.

Animal Intelligence

A REMARKABLE instance of animal intelligence has lately come under my notice, which I venture to relate as being possibly of interest to the readers of NATURE. In a neighbour's bungalow in this district two of our common house-swallows (*Hirundo javanica*) built their nest, selecting as their site for the purpose the top of a hanging lamp that hangs in the dining-room. As the lamp is either raised or depressed by chains fixed to a central counter-weight, these chains pass over pulleys fixed to a metal disk above, on which the nest was placed. The swallows evidently saw that, if the pulleys were covered with mud, moving the lamp either up or down would destroy the nest; so to avoid this natural result they built over each pulley a little dome, allowing sufficient space, both for wheel and chain to pass in the hollow so constructed, without danger to the nest, which was not only fully constructed, but the young birds were reared without further danger. This is, in my opinion, a wonderful example of adaptation to environment, and showing a step far beyond what may be contended as instinct only.

I may here add another curious case which seems to point to another branch of reasoning. During the dry weather I have been constantly annoyed by wasps building up with mud key-holes, sometimes keys, blank cartridge cases, and even in one case a *pen-holder*. As I did not care to have my gun charged with young wasps, I used to empty out any cartridge case which I found closed up with mud, but one cartridge-case in particular I noticed had been selected. This one I had left on my office table, and each time the wasp closed it up I drew the charge of mud and "grubs," &c.; but as frequently the wasp closed it up again. I may here mention that the wasp used to deposit the egg, and several small grubs in a cell, close over the top, and repeat the operation again till the cartridge was full, when the mouth would be pasted over with a lid of mud. As I repeatedly knocked out the grub and mud, it appears the wasp started a fresh plan. I noticed somewhat to my surprise that the mouth of a cartridge I had but a few hours before emptied was pasted over, so I thought it would be interesting to see how many grubs the wasp had secured in so short a time. I therefore removed the fresh lid, that was still damp, and discovered nothing inside! I am unable to say if this was done to direct my attention to one particular cartridge case or not, while another spot was being used, but I am inclined to believe such to have been the case, for later I noticed a gap made between two bundles of letters in one of my pigeon-holes, well built up with mud, and, of course, as well packed with grubs.

Ballangoda, Ceylon, June 14 FREDERICK LEWIS

Deafness and Signs

IN my studies with regard to the sign-languages I have, like others, turned some attention to cases of deafness. In such cases the use of signs, not the finger alphabet, but natural or conventional signs, such as are used by Indians or by deaf-mutes of themselves, have appeared to me to give particular satisfaction to the sufferer. The nervousness attendant upon attempting to make out what is said being avoided, the relief is very great, and more attention is given to what is spoken. Of course such aid to those untrained is but partial, and English people accustomed solely to the use of speech are rather unapt, but nevertheless signs are valuable auxiliaries, and will be found worth trying. Individuals vary in their capability, but inasmuch as many children pass through a period of sign-language, there will be many cases of adaptability. Whoever has watched deaf-mutes conversing, without the finger alphabet or without lip-reading, will recognise the satisfaction they receive from their intercourse by signs. My only object is to call attention to what has been found by experience to be an acceptable help, and which may be extended in its application.

HYDE CLARKE

The Duration of Germ-Life in Water

A RECENT announcement by Messrs. Crookes, Odling, and Tidy, that *Bacillus anthracis* in water approximately devoid of nutrient material after "a few hours" loses its power to multiply in suitable culture-media, induces me to send you a note of my own results in the same domain.

My observations were commenced in 1877, but were shortly afterwards suspended and not resumed in earnest until May 1885.

So far I have worked only with the various forms of organisms which chanced to be present in the water—usually distilled—employed. For a *preliminary* investigation I regard this as preferable to operating on pure cultures; one is more likely to be concerned with organisms of aqueous habitat naturally, and one sees which kinds predominate from time to time, and which survive.

In dealing with an indefinite variety of micro organisms it is necessary, of course, to be extremely rigid in one's precautions to guard against intrusion of foreign germs, an intrusion which cannot be detected as in the case of pure cultures. On this account I abandoned my original *modus operandi*—it was almost identical with that of Mr. Crookes and his colleagues—and adopted the arrangement of tubes described and figured in a paper by Mr. Blunt and myself in *Proc. Roy. Soc.*, vol. xxviii. p. 202.

Of a series of such tubes containing distilled water, originally rich in germ-life, kept at a temperature varying from 18° C. to 21° C., and examined at intervals from May 2, 1885, down to now, I find that in every one micro-organisms have sooner or later developed on the addition of the nutrient material.

Each tube is a microcosm, and it has been most interesting to observe how, as elsewhere, as time went on, the first dominant form has grown more and more feeble, until it seems to have become extinct, and is now succeeded by races of quite different kind. Whether the new order will yet give place to others remains to be seen. I can at any rate say confidently that micro-organisms vary greatly in the duration of their life in distilled water, and that some forms may survive for at least fourteen months in that medium at an ordinary temperature.

Chelmsford, July 19 ARTHUR DOWNES

The Bagshot Beds

IN reply to the letter from Mr. Irving in NATURE of July 8 (p. 217), I beg to state that a mere abstract of the paper on the Bagshot Beds by Mr. Herries and myself was read at the meeting of the Geological Society on June 9, on which occasion Mr. Irving was not present; that the report of our remarks in NATURE of July 1 (p. 210) only purports to give the conclusions at which we arrive, and not the evidence by which they are supported. We trust therefore that your readers will reserve their judgment until the entire paper is published.

A Lubricant for Brass Work

MANY besides myself have probably been inconvenienced by the corrosive action of ordinary lubricants—lard, grease, &c.—upon brass and copper, which causes the plugs of stop-cocks to leak or get fixed in their places, and does much damage to air-pump plates.

Melted india-rubber answers fairly, but it has too little "body," and too much glutinosity; moreover, it does, undoubtedly, in course of time, harden into a brittle, resinous substance. Vaseline is quite without action on brass, and never hardens; but it has not sufficient tenacity and adhesiveness.

A mixture of two parts by weight of vaseline (the common thick brown kind) and one part of melted india-rubber seems to combine the good qualities of both without the drawbacks of either.

The india-rubber should, of course, be pure (not vulcanised), and should be cut up into shreds and melted at the lowest possible temperature in an iron cup, being constantly pressed

down against the hot surface and stirred until a uniform glutinous mass is obtained. Then the proper weight of vaseline should be added, and the whole thoroughly stirred together.

This may be left on an air-pump plate for at any rate a couple of years without perceptible alteration either in itself or the brass.

Eton College

Butterflies' Wings

CAN you inform me of any method of relaxing the wings of butterflies allowed to stiffen in the closed state?

Stretford, Manchester, July 1 J. M. B.

[If the butterflies are laid on damp sand under cover of a bell-glass or other air-tight covering they will soon relax so as to be fit for setting-out. A drop or two of carbolic acid on a sponge should be placed with them in order to prevent mouldiness. —ED.]

NOTE ON THE ABSORPTION SPECTRUM OF DIDYMIUM

IN a paper on "Radiant Matter Spectroscopy" (Part 2, Samarium),[1] I said that in fractionation of the didymium earths with ammonia—"After a time a balance seemed to be established between the affinities at work, when the earths would appear in the same proportion in the precipitate and in the solution. At this stage they were thrown down by ammonia, and the precipitated earths set aside to be worked up by the fusion of their anhydrous nitrates so as to alter the ratio between them, when fractionation by ammonia could be again employed."

That in most methods of fractionation a rough sort of balance of affinities beyond which further separation by the same method is difficult, appears to be a general rule. I have long noticed this action when fractionating with ammonia, with oxalic and nitric acids, and with formic acid. The valuable point which renders this fact noteworthy is that the balance of affinities revealed by fractionation is not the same with each method. It was in consequence of the experience gained in these different methods of fractionation that I wrote in my paper read before the Royal Society, June 10 last (*Chemical News*, vol. liv. p. 13), after saying that I had not been able to separate didymium into Dr. Auer's two earths, "probably didymium will be found to split up in more than one direction according to the method adopted."

In illustration of this I may mention that, although I have not split up didymium into the two earths, or groups of earths, which are described by Dr. Auer, other processes of fractionation give me, so to speak, other cleavage planes or lines of scission through the compound molecule didymium.

According to Dr. Auer, a line in the well-known yellow band, close to the soda line, but less refrangible (w.l. about 579), is a component of the absorption-spectrum of neodymium, and therefore, under all conditions, its intensity should follow the same variations as the other bands of neodymium in the blue (wave-lengths 482, 469, 444). Some of my didymium fractions, however, show that the line 579 does not follow the same law as the other bands I have named. Thus, in a rather low fraction (+ 6) of the didymium earths from gadolinite and samarskite I found that the neodymium line 579 was of the same degree of blackness as the adjacent praseodymium line in the yellow (wave-length about 571), but the bands in the blue of neodymium had almost disappeared. In the adjacent fractions of didymium I was enabled, by appropriate dilution, to keep this set of bands in the yellow as a standard, of exactly the same intensity; it was now seen that in successive fractions the intensities of the other more refrangible lines belonging both to neodymium and praseodymium varied greatly from strong to almost obliteration, the bands in the yellow always being kept of the same intensity.

Didymium prepared from a specimen of fluocerite differed somewhat from the other didymiums. Here the band 579 (ascribed to neodymium) was very strong, the band in the yellow of praseodymium (571) slightly weaker, and the bands in the blue of neodymium (482, 469, and 444) easily visible. On diluting the solution the bands in the blue of neodymium and the one component of praseodymium in the yellow (571) appeared to follow the same law in becoming fainter and fainter with dilution, whilst the other component band in the yellow of neodymium (579) remained unaffected.

It seems to me that a possible explanation of this variation might be founded on the great strength of the bands in the yellow, and that the two fractions of didymium then under examination might differ only in the fact that one was slightly stronger than the other. To test this hypothesis I took the two fractions first experimented on, and putting each into a wedge-shaped cell of glass viewed them together in the spectroscope. (1) I adjusted the wedges so that the group in the yellow appeared to be of the same intensity in each spectrum. On examining other parts of the spectrum it was seen that in one solution the bands in the green were tolerably strong, and the bands in the blue scarcely visible, whilst in the other solution the bands in the green were very faint, and those in the blue quite absent. (2) The position of the wedges was adjusted so that the bands in the green in each case should be of equal intensities. It was now seen that the alteration had greatly upset the balance of the bands in the yellow, the solution in which the bands in the green were faintest before, now having much stronger yellow bands than the other. The explanation mentioned above therefore falls through, and I see no other way of accounting for the facts except in the supposition that by the mode of fractionation then adopted, didymium had split up in a different manner to what it would have done if the method of Dr. Auer had been followed.

The colour of the different fractions of didymium nitrate varies from a dark rose-red at the more basic end (+ 17) to amber at the less basic end (+ 4). These variations in colour do not necessarily accompany a difference in the absorption-bands, for in one instance an amber and a rose-coloured salt were found to have almost identical spectra.

It would almost appear from these experiments, coupled with the facts I brought forward in last week's *Chemical News* (p. 14), that the "one band, one element" theory I lately advanced in connection with the phosphorescent spectrum of yttrium, may probably hold good in the case of the group of elements forming absorption spectra. According to this hypothesis, therefore, neodymium and praseodymium must not be considered as actual chemical elements, but only the names given to two groups of molecules into which the complex molecule didymium splits up by one particular method of fractionation.

WILLIAM CROOKES

HEATING AND COOKING BY GAS

A FEW years ago the public was led to believe that the use of coal-gas for lighting purposes was on its trial, and must shortly give way to the electric light. Threatened institutions live long, and even if coal-gas is destined to be eventually superseded by electricity for lighting purposes, a useful future is now opening out for it as a fuel offering many advantages over coal for domestic heating and cooking. In these fields it may possibly occur in the future that coal-gas—unless the price is everywhere considerably reduced—will have to encounter rivals such as the petroleum oils on the score of their cheapness, but at present, coal-gas, for cooking

and heating purposes, offers many facilities and advantages over any other kind of fuel.

Gas Cooking Stoves.—Those who remember the gas cooking stoves which were offered to the public even a few years ago, will acknowledge that the modern stoves now manufactured have reached a very high degree of perfection. In nearly all the larger kinds of stove intended for a family of six or more persons, the sides and top of the oven are constructed of double walls, and packed with a non-conducting fire-proof material—generally slag wool—so that but little heat escapes from the exterior of the stove to be lost by radiation; the internal surfaces of the stoves are usually enamelled, and are thus preserved from rust and decay, and easily kept clean, and in addition in some ovens, the racks for suspending the grids from which the meat is hung, slide out or turn out on a hinge, and are thus more easily cleaned than when fixed in the oven. On the tops of the stoves are placed burners for boiling kettles and saucepans, and for stewing, and an invertible burner is sometimes added, which can be rotated so as to bring the flame underneath when it is intended to grill. The following points may be enumerated as those in which cooking by gas possesses decided advantages over the ordinary kitchen range:—(1) There are no dust or cinders, and the whole process is more cleanly; (2) in some of the best stoves the oven can be heated up to a high temperature—sufficient for making pastry—in a few minutes only after the gas is lighted; (3) the different degrees of heat necessary for cooking various articles can be easily attained by limiting or increasing the supply of gas to the oven burners, or by increasing or diminishing the ventilation of the oven by opening or closing the flue-valve; and this is a point which good cooks will especially appreciate.

The principal arguments adduced by the opponents of gas cooking may be stated to be:—(1) That the cost is greater; (2) that joints of meat baked in gas ovens smell or taste of gas; (3) that the fumes and smell of cooking are more perceptible from gas ovens than from ordinary kitchen ranges; (4) that there is no supply of hot water with a gas oven; (5) that the gas stove does not warm the kitchen. We will now proceed to consider these objections *seriatim*.

(1) Although there can be no doubt that more heat is obtained from coal by burning the same value than from gas, still if attention is paid to the stove, and the gas is turned off as soon as the cooking is finished, for ordinary sized households the difference in cost between cooking by gas and cooking by coal is hardly appreciable.

(2) We may class gas ovens as of two kinds, A and B. In A, rings or rows of burners are placed at the bottom of the oven, and the air of the oven is heated up, this heated air and the products of combustion of the gas passing over and baking the meat. The burners used are usually those which give a luminous flame, for the reason that the luminous flame, although not itself of so high a temperature as the non-luminous flame from the atmospheric burner, yet radiates more heat. This greater radiation of heat is, like the luminosity, due to the separation of solid particles of carbon in the flame which become incandescent. Thus we see that the luminous flame radiates more heat to the air of the oven than the non-luminous. But it is in this class of oven especially that the baked meat smells or tastes of gas, as it is liable to become sodden with the steam and other products of combustion of the gas jets which pass over it, and no amount of ventilation of the oven will entirely cure this defect. In the other class of ovens, B, the burners are placed in rows at the bottom and along the sides of the oven walls. The oven walls are heated by the flames, and when hot radiate the heat to the joint of meat, which is thus baked by radiant heat as well as by hot air. The products of combustion of the gas jets pass up the sides of the oven and escape by the flue at the back without contaminating the meat. Atmospheric burners are almost invariably used in this class of oven, because the non-luminous flame is hotter than the luminous, and more quickly heats the oven wall, although less heat is radiated from the flame itself. The atmospheric burners have also this advantage, that the gas being mixed with twice its volume of air, the hydrogen and carbon are burnt at the same time, and no solid particles of carbon are formed, and thus there can be no soot from imperfect combustion, as so often happens in the luminous flame, in which the hydrogen of the hydrocarbons burns before the carbon, which is separated into small solid particles and strongly heated up before being finally burnt to carbonic acid. Consequently meat baked in this class of oven is not distinguishable from a joint roasted before an open fire.

(3) If a flue is carried up from the top of the back part of the oven into the kitchen chimney, the fumes from the oven cannot enter the general air of the kitchen. In all gas apparatus of whatever sort, some means must be provided for carrying off the products of combustion of the gas, and this is especially necessary in the case of gas cooking stoves. Ventilation of the oven is obtained by air passing in from below to ascend and escape with the products of combustion by the flue. The valve guarding the flue outlet is capable of regulating the ventilation, and is usually so constructed that it cannot entirely close the flue.

(4) The larger gas cooking stoves are now very usually supplied with boilers, which can be attached to the side of the stove, and can be heated below by a ring of atmospheric burners. [The burners at the top of the stove for boiling kettles and saucepans, making toast, grilling, and stewing, should also be atmospheric.] There can be no doubt that for heating a large supply of water, gas is not economical as compared with coal, but these boilers have this great advantage that they can be easily inspected and cleaned, and the fur—caused by the deposit of lime salts where the water to be heated is hard—can be easily removed. In towns and districts which are supplied with hard water (containing much carbonate of lime in solution), the ordinary kitchen boiler must be opened occasionally to remove the fur—a proceeding causing much inconvenience. If the fur deposit is allowed to accumulate too long an explosion may take place. This may happen in one of two ways; either the mouth of the supply pipe may become choked, cutting off the water from the boiler, or the boiler plates having become much heated, whilst the water in the boiler is cool owing to the intervention of a thick non-conducting layer of fur, if this deposit should crack, the cold water coming suddedly into contact with the red hot iron would cause a dangerous evolution of steam. The boilers sent out with gas cooking stoves can supply hot water for the kitchen only; they are not made to give a hot water supply under pressure available at any part of the house, as is the ordinary kitchen high-pressure boiler, so that for upstairs bath and lavatory purposes, hot water must be obtained from some form of gas bath-heater, of which we will speak presently.

(5) The gas stoves now made—being well packed and losing but little heat by radiation—certainly do not warm the general air of the kitchen as the kitchen fire does, and this negative quality in summer is a great advantage, as the kitchen remains cool instead of being at the usual unbearable temperature. In winter, if the kitchen fire is retained, this should be lighted early in the day until the room is warm, or some form of gas fire may be used—or it is even possible now to obtain a gas stove combining an open gas fire below, in front of which a small joint may be roasted, with a small gas oven above. The open gas fire will sufficiently warm a small kitchen.

The consumption of gas in a stove of the size required for a family of nine or ten persons varies from 15 to 20 cubic feet per hour (at an average pressure of 8/10) if the

oven burners alone are lighted and turned full on. In most cooking operations the amount of gas required would be only two-thirds of these quantities; the supply of gas being easily regulated to this or any other amount. If all the top burners in addition be lighted and turned full on, the average run of gas is from 40 to 60 cubic feet per hour. Twenty feet an hour for six hours a day is a fair representation of the amount of cooking required in a middle class family of ten persons. At 3*s*. per 1,000 cubic feet, this would entail an expenditure of 4·32*d*. per day, or 2*s*. 6¼*d*. per week, or 1*l*. 12*s*. 9¼*d*. per quarter. To raise a gallon of water in a copper boiler from 50° F. to 170° F., requires on the average a consumption of about 3 feet of gas, so that if very much hot water is required for culinary or domestic purposes the gas bill may be expected to show a corresponding increase.

Cooking by gas will not be introduced all at once. Gas stoves are now very generally obtained to supplement the kitchen range, for which purpose they are excellently adapted; and as their possibilities and advantages are more clearly appreciated they will no doubt come into more general use. We have indicated some of the chief points in their construction and management, and while we do not advise any one utterly to discard coal fires for cooking, we would recommend a trial of gas as being likely, where it can be obtained of good quality at moderate prices, and where the stoves will be treated with care and attention, to be found economical, cleanly, and useful.

Water and Bath-heaters.—In a house where gas is entirely used for heating and cooking, or where there is no high-pressure kitchen boiler connected with a hot water cistern by circulating pipes, capable of giving a supply of hot water on the upper floors, one of these appliances will be found very useful. There are numerous forms of this apparatus, and most of them are contrived in a very ingenious manner. The plan usually adopted is to receive the cold water at the top of the apparatus—which is of copper or copper tin-lined—where it is spread out in the form of spray or thin films to pass slowly down over surfaces of copper, receiving in its passage the necessary heat from gas burners below, to the bottom of the apparatus, where it flows out by a spout. The temperature of the issuing water will vary with the quantity of gas consumed and with the flow of the water, *i.e.* the amount passing through the apparatus in a given time. The object generally aimed at is to obtain a bath of 30 gallons of water at 100° F. in twenty minutes or thereabouts. For this purpose the water must be heated to about 105°, as when in the bath it gradually cools whilst this is filling. In the best forms of bath-heater, 25 to 30 cubic feet of gas must be consumed—at ordinary pressures, 7/10 to 10/10—to raise 30 gallons of water from 50° to 100° in 15 or 20 minutes. Here then we have an apparatus which at the cost of little more than 1*d*. is capable of providing ample material for a good warm bath. We would unhesitatingly recommend these bath-heaters, were it not the custom of most of the makers—with one or two exceptions however—to send them out without any flues or chimneys, and even sometimes to assert that no flue is necessary, as there is no smoke, and nothing unpleasant is produced by the combustion of the gas. There have however been some very unpleasant consequences from taking a bath in a small highly heated room, the air of which was loaded with carbonic acid—fainting and even partial asphyxia having been recorded under these circumstances. That the danger is no imaginary one will be seen when we consider that if in a room containing 500 cubic feet of space—the size of very many bath rooms—50 cubic feet of carbonic acid are produced by burning 25 cubic feet of coal-gas, the percentage of carbonic acid in the air is raised from ·04 to 10, and the entire oxygen of 200 cubic feet of air is destroyed. Fatal results have been known from the inhalation, even for a short period, of air containing 10 per cent. of carbonic acid. The temperature of the air of the room will also be very much raised, and will tend to help in the production of perhaps fatal syncope. We cannot then too strongly insist on the absolute necessity of providing a flue to carry off the products of combustion to the outer air of an apparatus which can produce such an enormous volume of carbonic acid in so short a space of time. The flue should be carried into a chimney with a good draught, as the escaping products are generally much cooled down by having parted with much of their heat to the water flowing through the apparatus. There are other varieties of water-heater constructed for various purposes, only one of which we are able to notice in the present article. This is a spiral water-heater for lavatories, the invention of Mr. Fletcher. In two minutes this little apparatus, at a cost of half a foot of gas, can raise nearly two quarts of water to 100° F. It is an ingenious contrivance, and free from the objections attending most of the larger apparatus described above.

Gas Fires.—These may be classified as radiation stoves, the room being heated entirely by radiation; and ventilation stoves, warm air issuing from the stove and displacing the colder air of the room. But many of these latter also warm the room by radiation from the incandescent asbestos or from the warm sides of the stove. Mr. Fletcher has calculated that with gas at 3*s*. per 1000 cubic feet, his open incandescent radiation gas fires cost for the same work about as much as coal fires when the coal is 30*s*. per ton, but with ventilating stoves the cost is about two-thirds of this. As in cooking by gas however, there are no dust, dirt, or cinders, and the fire can be immediately lighted or extinguished and requires no attention when alight. Nearly all the patterns of radiation stove now made depend on the heating of fibre or lump asbestos by non-luminous flames from atmospheric burners. The average consumption of gas required to maintain a room containing 5000 or 6000 cubic feet of space at a suitable temperature in winter, varies between 12 to 20 cubic feet per hour, depending on a large variety of circumstances. Most people when sitting in a room prefer to be warmed by radiant heat, as from an ordinary open coal fire, and to leave the ventilation of the room to accidental circumstances—which usually means a cold draught along the floor towards the fire. Ventilation stoves, if they fulfil the proper conditions, are certainly better adapted for warming large apartments, such as shops, workrooms, and halls, than radiation stoves. The conditions to be fulfilled are that the air be taken from a pure source in the outer atmosphere, that it be warmed by its passage through the stove, but not overheated or burnt—as is so often the case—and that it enter the room in an ascending direction towards the ceiling. In many cases it may be necessary that the air, rendered dry by its passage through the stove, should be moistened by passing over a tray of water before entering the general air of the room. Radiation stoves are perhaps better suited for private houses, especially for bed rooms and other apartments where a fire is only occasionally required. The flues of these stoves should open into the chimney at the back of the fireplace. The temperature of the air and products of combustion escaping through the flue will generally be found very high, but the heat thus lost is necessary to create a draught up the chimney, and assists in the ventilation of the room.

It has been said that the more general adoption of gas for heating and cooking would solve the smoke difficulty in London and those large towns where domestic and not factory smoke is the chief offender. A London pea-soup fog is certainly due to the coating of the particles of moisture suspended in the mist with "a carbonaceous sulphurous cuticle" as Mr. Harold Dixon has expressed it, and by preventing the daily evolution of millions of small particles of unconsumed carbon from our chimneys, we

should do away with the acrid yellow character of our fogs. But the mists due to the position of London on the estuary of a large river, would remain to the same extent as now, and there would still be the same amount of sulphurous acid given off into the air to be precipitated with the rain as sulphuric acid, and carry on its work of destruction on building stones and mortar. One cubic foot of coal-gas produces on combustion 0·2 to 0·5 grains of sulphurous acid, so that the amount evolved would continue to be, as now, enormous. Still the air would be deprived of its sooty particles to a great extent, and the old familiar features, characteristic of grimy London, might in time disappear. The carbonic acid which is the chief product in the combustion of coal-gas, is diffused at once into the general body of the atmosphere, and the marvellous rapidity with which this is effected is revealed to us when we know that the air of our open streets and parks differs only by the most minute quantities—if at all—in its contained carbonic acid, from the air of the mountains or the sea.

THE TOPOGRAPHIC FEATURES OF LAKE SHORES[1]

Introduction

THE play of meteoric agents on the surface of the land is universal, and there is a constant tendency to the production of the forms characteristic of their action. All other forms are of the nature of exceptions, and attract the attention of the observer as requiring explanation. The shapes wrought by atmospheric erosion are simple and symmetric, and need but to be enumerated to be recognised as the normal elements of the sculpture of the land. Along each drainage line there is a gradual and gradually increasing ascent from mouth to source, and this law of increasing acclivity applies to all branches as well as to the main stem. Between each pair of adjacent drainage lines is a ridge or hill standing about midway and rounded at the top. Wherever two ridges join there is a summit higher than the adjacent portion of either ridge; and the highest summits of all are those which, measuring along lines of drainage, are most remote from the ocean. The crests of the ridges are not horizontal, but undulate from summit to summit. There are no sharp contrasts of slope; the concave profiles of the drainage lines change their inclination little by little, and they merge by a gradual transition in the convex profiles of the crests and summits. The system of slopes thus succinctly indicated is established by atmospheric erosion under the general law of the interdependence of parts. It is the system which opposes the maximum resistance to the erosive agents.

The factor which most frequently, and in fact almost universally, interrupts these simple curves is heterogeneity of terrane or diversity of rock texture. Different rocks have different powers of resistance to erosion, and the system of declivities which, under the law of interdependence, adjusts itself to diversity of rock texture, is one involving diversity of form. Hard rocks survive, while the soft are eaten away. Peaks and cliffs are produced. Apices are often angular instead of rounded. Profiles exhibit abrupt changes of slope. Flat-topped ridges appear, and the distribution of maximum summits becomes in a measure independent of the length of drainage lines.

A second factor interrupting the continuity of erosion profiles is upheaval, and this produces its effect in two distinct ways. First, the general uprising of a broad tract of land affects the relation of the drainage to its point of discharge or to its base level, causing corrosion by streams to be more rapid than the general waste of the surface, and producing cañons and terraces. Second, a local uprising by means of a fault produces a cliff at the margin of the uplifted tract, and above this cliff there is sometimes a terrace.

A third disturbing factor is glaciation, the *cirques* and moraines of which are distinct from anything wrought by pluvial erosion; and a fourth is found in eruption.

The products of all these agencies except the last have been occasionally confused with the phenomena of shores. The beach-lines of Glen Roy have been called river terraces. The cliffs of the Downs of England have been ascribed to shore waves. Glacial moraines in New Zealand have been interpreted as shore terraces. Beach ridges in our own country have been described as glacial moraines, and fault terraces as well as river terraces have been mistaken for shore marks. Nevertheless, the topographic features associated with shores are essentially distinct from all others; and when their peculiar characters are understood there is little occasion for confusion. It is only where the shore record is faintly drawn that any difficulty need arise in its interpretation. In investigating the history of Lake Bonneville and other Quaternary water bodies of the Great Basin, the writer and his assistants have had constant occasion to distinguish from all others the elements of topography having a littoral origin and have become familiar with the criteria of discrimination. Their endeavour to derive from the peculiarities of the old shore lines the elements of a chronology of the lake which wrought them, has led them to study also the genesis of each special feature.[1]

In the discussion of shore phenomena there is little room for originality. Not only has each of the elements which go to make up the topography of a shore been recognised as such, but its mode of origin has been ascertained. There appears, however, to be room for a systematic treatment of the subject in English, for it is only in continental Europe that its general discussion has been undertaken. The writings of Elie de Beaumont include a valuable contribution,[2] and Alessandro Cialdi has devoted a volume to the motion of waves and their action on coasts.[3] These cover a large portion of the ground of the present essay, but treat the subject from points of view so diverse that the essay would be only partially superseded by their translation. The title of a work by H. Keller ("Studien über die Gestaltung der Sandküsten") indicates another discussion of a general nature, but this I have not seen. American and British contributions are contained chiefly in the reports of engineers on works for the improvement of harbours and the defence of coasts. The most comprehensive which has fallen under my eye, and one, at the same time, of the highest scientific character, is contained in the annual report of the United States Coast Survey for 1869, where Prof. Henry Mitchell, in treating of the reclamation of tide lands, describes the formation of the barriers of sand and shingle by which these are separated from the ocean.

It is proper to add that the writer became acquainted with these works only after the body of this essay was prepared. The objective studies on which his conclusions are based had been completed, and the discussion had acquired nearly its present shape before he became aware of the extent of the affiliated literature. His conclusions have, therefore, the quality of independence, and, so far as they coincide with those of earlier writers, have a corroborative value.

The engineering works whose construction has led to local investigations of shores are chiefly upon maritime coasts, where tides exert an important influence, and the literature of lake shores is comparatively meagre. It is

[1] From a paper by Mr. G. K. Gilbert in the "Fifth Annual Report of the Geological Survey of the United States for 1883-84." (Washington, 1885.)

[1] Partial outlines of the subject have been presented by the writer in connection with various accounts of Lake Bonneville, and a fuller outline was published by Mr. I. C. Russell in a paper on Lake Lahontan in the "Third Annual Report of the Geological Survey."

[2] "Leçons de géologie pratique;" tome premier; septième leçon, "Levées de sable et de galet," pp. 221-52.

[3] "Sul moto ondoso del mare e su le correnti di esso specialmente su quelle littorali pel comm" Alessandro Cialdi. Roma, 1866.

true that the phenomena of lake margins are closely paralleled by those of tide-washed coasts, but this, unfortunately, does not render the literature of the latter the more applicable, for there is a tendency to ascribe to the action of tides features which the students of inland lakes are compelled to account for independently of that agent.

It should be noted also that the point of view of the civil engineer is somewhat different from that of the present study. He is, indeed, concerned with all the forms into which the shore material is wrought by the action of the waves, but he is not at all concerned with their internal structure; and he knows them, moreover, only as subaqueous banks to be determined by sounding, and not at all as features of the dry land. The geologic student has, too, some facilities for study which the engineer lacks, for he is frequently enabled to investigate the anatomy of shore structures by means of natural cross-sections, while the engineer is restricted to an examination of their superficial forms.

Earth Shaping

The earth owes its spheroidal form to attraction and rotation. It owes its great features of continent and ocean bed to the unequal distribution of the heterogeneous material of which it is composed. Many of its minor inequalities can be referred to the same cause, but its details of surface are chiefly moulded by the circulation of the fluids which envelop it. This shaping or moulding of the surface may be divided into three parts—subaërial shaping (land sculpture), subaqueous shaping, and littoral shaping. In each case the process is threefold, comprising erosion, transportation, and deposition.

In subaërial or land shaping the agents of erosion are meteoric—rain, acting both mechanically and chemically, streams, and frost. The agent of transportation is running water. The condition of deposition is diminishing velocity.

In subaqueous shaping, or the moulding of surface which takes place beneath lakes and oceans, currents constitute the agent of erosion. They constitute also the agent of transportation; and the condition of deposition is, as before, diminishing velocity.

In littoral shaping, or the modelling of shore features, waves constitute the agent of erosion. Transportation is performed by waves and currents acting conjointly, and the condition of deposition is increasing depth.

On the land the amount of erosion vastly exceeds the amount of deposition. Under standing water erosion is either *nil* or incomparably inferior in amount to deposition. And these two facts are correlatives, since the product of land erosion is chiefly deposited in lakes and oceans, and the sediments of lakes and oceans are derived chiefly from land erosion. The products of littoral erosion undergo division, going partly to littoral deposition and partly to subaqueous deposition. The material for littoral deposition is derived partly from littoral erosion and partly from land erosion.

That is to say, the detritus worn from the land by meteoric agents is transported outward by streams. Normally it is all carried to the coast, but owing to the almost universal complication of erosion with local uplift, there is a certain share of detritus deposited upon the basins and lower slopes of the land. At the shore a second division takes place, the minor portion being arrested and built into various shore structures, while the major portion continues outward and is deposited in the sea or lake. The product of shore erosion is similarly divided. A part remains upon the shore, where it is combined with material derived from the land, and the remainder goes to swell the volume of subaqueous deposition.

The forms of the land are given chiefly by erosion. Since the wear by streams keeps necessarily in advance of the waste of the intervening surfaces, and since, also, there is inequality of erosion dependent on diversity of texture, land forms are characterised by their variety.

The forms of sea beds and lake beds are given by deposition. The great currents by which subaqueous sediments are distributed sweep over the ridges and other prominences of the surface and leave the intervening depressions comparatively currentless. Deposition, depending on retardation of currents, takes place chiefly in the depressions, so that they are eventually filled and a monotonous uniformity is the result.

The forms of the shore are intermediate in point of variety between those of the land and those of the sea bed; and since they alone claim parentage in waves, they are *sui generis*.

Ocean shores are genetically distinguished from lake shores by the co-operation of tides, which cannot fail to modify the work accomplished by waves and wind currents. The shores which constitute the objective basis of the present discussion were tideless; and the discussion is therefore limited to lake shores. It is perhaps to be regretted that the systematic treatment here proposed could not be extended so as to include all shores, but there is a certain compensation in the fact that the results reached in reference to lake shores have an important negative bearing on tidal discussions. It was long ago pointed out by Élie de Beaumont[1] and Desor[2] that many of the more important features ascribed by hydraulic engineers to tidal action, are produced on the shores of inland seas by waves alone; and the demonstration of wave-work pure and simple should be serviceable to the maritime engineer by pointing out the results in explanation of which it is unnecessary to appeal to the agency of tides.

CAPILLARY ATTRACTION

THE heaviness of matter had been known for as many thousand years as men and philosophers had lived on the earth, but none had suspected or imagined, before Newton's discovery of universal gravitation, that heaviness is due to action at a distance between two portions of matter. Electrical attractions and repulsions, and magnetic attractions and repulsions, had been familiar to naturalists and philosophers for two or three thousand years. Gilbert, by showing that the earth, acting as a great magnet, is the efficient cause of the compass needle's pointing to the north, had enlarged people's ideas regarding the distances at which magnets can exert sensible action. But neither he nor any one else had suggested that heaviness is the resultant of mutual attractions between all parts of the heavy body and all parts of the earth, and it had not entered the imagination of man to conceive that different portions of matter at the earth's surface, or even the more dignified masses called the heavenly bodies, mutually attract one another. Newton did not himself give any observational or experimental proof of the mutual attraction between any two bodies, of which both are smaller than the moon. The smallest case of gravitational action which was included in the observational foundation of his theory, was that of the moon on the waters of the ocean, by which the tides are produced; but his inductive conclusion that the heaviness of a piece of matter at the earth's surface, is the resultant of attractions from all parts of the earth acting in inverse proportion to squares of distances, made it highly probable that pieces of matter within a few feet or a few inches attract one another according to the same law of distance, and Cavendish's splendid experiment verified this conclusion. But now for our question of this evening. Does this attraction between any particle of

[1] "Leçons de Géologie pratique," Paris, 1845, v. i. p. 232.
[2] "Geology of Lake Superior Land District," by Foster and Whitney, Washington, 1851, v. ii. pp. 262, 266.

matter in one body and any particle of matter in another continue to vary inversely as the square of the distance, when the distance between the nearest points of the two bodies is diminished to an inch (Cavendish's experiment does not demonstrate this, but makes it very probable), or to a centimetre, or to the hundred-thousandth of a centimetre, or to the hundred-millionth of a centimetre? Now I dip my finger into this basin of water; you see proved a force of attraction between the finger and the drop hanging from it, and between the matter on the two sides of any horizontal plane you like to imagine through the hanging water. These forces are millions of times greater than what you would calculate from the Newtonian law, on the supposition that water is perfectly homogeneous. Hence either these forces of attraction must, at very small distances, increase enormously more rapidly than according to the Newtonian law, or the substance of water is not homogeneous. We now all know that it is not homogeneous. The Newtonian theory of gravitation is not surer to us now than is the atomic or molecular theory in chemistry and physics; so far, at all events, as its assertion of heterogeneousness in the minute structure of matter apparently homogeneous to our senses and to our most delicate direct instrumental tests. Hence, unless we find heterogeneousness and the Newtonian law of attraction incapable of explaining cohesion and capillary attraction, we are not forced to seek the explanation in a deviation from Newton's law of gravitational force. In a little communication to the Royal Society of Edinburgh twenty-four years ago,[1] I showed that heterogeneousness does suffice to account for any force of cohesion, however great, provided only we give sufficiently great density to the molecules in the heterogeneous structure.

Nothing satisfactory, however, or very interesting mechanically, seems attainable by any attempt to work out this theory without taking into account the molecular motions which we know to be inherent in matter, and to constitute its heat. But so far as the main phenomena of capillary attraction are concerned, it is satisfactory to know that the complete molecular theory could not but lead to the same resultant action in the aggregate as if water and the solids touching it were each utterly homogeneous to infinite minuteness, and were acted on by mutual forces of attraction sufficiently strong between portions of matter which are exceedingly near one another, but utterly insensible between portions of matter at sensible distances. This idea of attraction insensible at sensible distances (whatever molecular view we may learn, or people not now born may learn after us, to account for the innate nature of the action), is indeed the key to the theory of capillary attraction, and it is to Hawksbee[2] that we owe it. Laplace took it up and thoroughly worked it out mathematically in a very admirable manner. One part of the theory which he left defective—the action of a solid upon a liquid, and the mutual action between two liquids—was made dynamically perfect by Gauss, and the finishing touch to the mathematical theory was given by Neumann in stating for liquids the rule corresponding to Gauss's rule for angles of contact between liquids and solids.

Gauss, expressing enthusiastic appreciation of Laplace's work, adopts the same fundamental assumption of attraction sensible only at insensible distances, and, while proposing as chief object to complete the part of the theory not worked out by his predecessor, treats the dynamical problem afresh in a remarkably improved manner, by founding it wholly upon the principle of what we now call potential energy. Thus, though the formulas in which he expresses mathematically his ideas are scarcely less alarming in appearance than those of Laplace, it is very easy to translate them into words by which the whole theory will be made perfectly intelligible to persons who imagine themselves incapable of understanding sextuple integrals. Let us place ourselves conveniently at the centre of the earth so as not to be disturbed by gravity. Take now two portions of water, and let them be shaped over a certain area of each, call it A for the one, and B for the other, so that when put together they will fit perfectly throughout these areas. To save all trouble in manipulating the supposed pieces of water, let them become for a time perfectly rigid, without, however, any change in their mutual attraction. Bring them now together till the two surfaces A and B come to be within the one-hundred-thousandth of an inch apart, that is, the forty-thousandth of a centimetre, or two hundred and fifty micro-millimetres (about half the wave-length of green light). At so great a distance the attraction is quite insensible: we may feel very confident that it differs, by but a small percentage, from the exceedingly small force of attraction which we should calculate for it according to the Newtonian law, on the supposition of perfect uniformity of density in each of the attracting bodies. Well known phenomena of bubbles, and of watery films wetting solids, make it quite certain that the molecular attraction does not become sensible until the distance is much less than 250 micro-millimetres. From the consideration of such phenomena Quincke (*Pogg. Ann.*, 1869) came to the conclusion that the molecular attraction does become sensible at distances of about fifty micro-millimetres. His conclusion is strikingly confirmed by the very important discovery of Reinold and Rücker that the black film, always formed before an undisturbed soap bubble breaks, has a uniform or nearly uniform thickness of about eleven or twelve micro-millimetres. The abrupt commencement, and the permanent stability, of the black film demonstrate a proposition of fundamental importance in the molecular theory:—The tension of the film, which is sensibly constant when the thickness exceeds fifty micro-millimetres, diminishes to a minimum, and begins to increase again when the thickness is diminished to ten micro-millimetres. It seems not possible to explain this fact by any imaginable law of force between the different portions of the film supposed homogeneous, and we are forced to the conclusion that it depends upon molecular heterogeneousness. When the homogeneous molar theory is thus disproved by observation, and its assumption of a law of attraction augmenting more rapidly than according to the Newtonian law when the distance becomes less than fifty micro-millimetres is proved to be insufficient, may we not go farther and say thet it is unnecessary to assume any deviation from the Newtonian law of force varying inversely as the square of the distance continuously from the millionth of a micro-millimetre to the remotest star or remotest piece of matter in the universe; and, until we see how gravity itself is to be explained, as Newton and Faraday thought it must be explained, by some continuous action of intervening or surrounding matter, may we not be temporarily satisfied to explain capillary attraction merely as Newtonian attraction intensified in virtue of intensely dense molecules movable among one another, of which the aggregate constitutes a mass of liquid or solid.

But now for the present, and for the rest of this evening, let us dismiss all idea of molecular theory, and think of the molar theory pure and simple, of Laplace and Gauss. Returning to our two pieces of rigidified water left at a distance of 250 micro-millimetres from one another. Holding them in my two hands, I let them come nearer and nearer until they touch all along the surfaces A and B. They begin to attract one another with a force which may be scarcely sensible to my hands when their distance apart is fifty micro-millimetres, or even as little as ten micro-millimetres; but which certainly becomes sensible when the distance becomes one micro-millimetre, or the fraction of a micro-millimetre; and enormous, hundreds or thousands of kilogrammes' weight, before they come into absolute contact. I am supposing the area of each

[1] *Proceedings* of the Royal Society of Edinburgh, April 21, 1862 (vol. iv.).
[2] Royal Society *Transactions*, 1709-13.

of the opposed surfaces to be a few square centimetres. To fix the ideas, I shall suppose it to be exactly thirty square centimetres. If my sense of force were sufficiently metrical I should find that the work done by the attraction of the rigidified pieces of water in pulling my two hands together was just about four and a half centimetre-grammes. The force to do this work, if it had been uniform throughout the space of fifty micro-millimetres (five-millionths of a centimetre) must have been nine hundred thousand grammes weight, that is to say, nine-tenths of a ton. But in reality it is done by a force increasing from something very small at the distance of fifty micro-millimetres to some unknown greatest amount. It may reach a maximum before absolute contact, and then begin to diminish, or it may increase and increase up to contact, we cannot tell which. Whatever may be the law of variation of the force, it is certain that throughout a small part of the distance it is considerably more than one ton. It is possible that it is enormously more than one ton, to make up the ascertained amount of

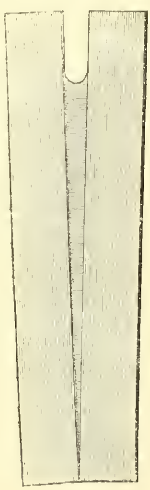

Fig. 1.

work of four and a half centimetre-grammes performed in a space of fifty micro-millimetres.

But now let us vary the circumstances a little. I take the two pieces of rigidified water, and bring them to touch at a pair of corresponding points in the borders of the two surfaces A and B, keeping the rest of these surfaces wide asunder (see Fig. 1). The work done on my hands in this proceeding is infinitesimal. Now, without at all altering the law of attractive force, let a minute film of the rigidified water become fluid all over each of the surfaces A and B: you see exactly what takes place. The pieces of matter I hold in my hands are not the supposed pieces of rigidified water. They are glass, with the surfaces A and B thoroughly clean and wetted all over each with a thin film of water. What you now see taking place is the same as what would take place if things were exactly according to our ideal supposition. Imagine, therefore, that there are really two pieces of water, all rigid, except the thin film on each of the surfaces A and B, which are to be put together. Remember also that the Royal Institution, in which we are met, has been, for the occasion, transported to the centre of the earth so that we are not troubled in any way by gravity. You see we are not troubled by any trickling down of these liquid films—but I must not say *down*, we have no up and down here. You see the liquid film does not trickle along these surfaces towards the table, at least you must imagine that it does not do so. I now turn one or both of these pieces of matter till they are so nearly in contact all over the surfaces A and B, that the whole interstice becomes filled with water. My metrical sense of touch tells me that exactly four and a half centimetre-grammes of work has again been done; this time, however, not by a very great force, through a space of less than fifty micro-millimetres, but by a very gentle force acting throughout the large space of the turning or folding-together motion which you have seen, and now see again. We know, in fact, by the elementary principle of work done in a conservative system, that the work done in the first case of letting the two bodies come together directly, and in the second case of letting them come together by first bringing two points into contact and then folding them together, must be the same, and my metrical sense of touch has merely told me in this particular sense what we all know theoretically must be true in every case of proceeding by different ways to the same end from the same beginning.

William Thomson

(*To be continued.*)

THE TOTAL SOLAR ECLIPSE, 1886 *AUGUST* 28–29

The Eclipse Expedition will leave England on the 29th inst. in the Royal Mail Steamship *Nile*, timed to arrive at Barbados on August 11. We regret to learn that Her Majesty's ship *Canada*, which was told off to assist the Expedition, chiefly by supplying artificers and assistance in camping and in the observations, has been withdrawn on some "diplomatic" service. This is a serious blow to the probabilities of good results.

From data supplied by Mr. Hind, the following details have been computed for the Island of Grenada:—

	Latitude N.	Longitude W.	Commencement of totality G.M.T.	Commencement of totality Local time
	° ′	° ′	h. m. s.	h. m. s.
Levera	12 13·5	61 37	23 17 19	19 10 51
Caliveny	12 0·0	61 43	23 17 14	19 10 22
Point Saline ...	12 0·5	61 48	23 17 10	19 9 58
Fort Frederick.	12 3·0	61 44	23 17 13	19 10 17

	Duration of totality	Sun's Azimuth	Sun's True altitude	Angle from N. point
	m. s.	° ′	° ′	
Levera	3 45	84 12	18 56	87° to W.
Caliveny	3 52	84 6	18 48	73° ,,
Point Saline ...	3 48	84 4	18 42	72° ,,
Fort Frederick.	3 49	84 3	18 46	77° ,,

The sun's altitude and azimuth and the angle from N. point are given for the commencement of totality.

The time of first contact for the middle of the island [assumed lat. 12° 6′·0, long. 61° 43′·0] is 18h. 11m. 55s. local mean time at 77°·0 N. to W. on the sun's limb; and ends at 20h. 20m. 44s. at 105° N. to E. on the limb.

A diagram is given below showing the position of the principal stars and planets at the commencement of totality. The distances of the planets from the sun are very roughly as follows (the positions of Mercury and Venus being shown absolutely, and the directions of the others indicated by arrows):—

Mercury (Me) = 4	Mars (Ma) = 15
Venus (V) = 6	Saturn (S) = 12

Jupiter (J), Uranus (U) almost in conjunction = 8.

Local mean time of transit of Polaris and δ Ursæ Minoris for Caliveny (Grenada), long. 61° 43′ W.:—

HORIZON

Diagram of configuration of stars and planets during the total solar eclipse, 1886 August 28-29, for Grenada. V = Venus; ME = Mercury; MA = Mars; J = Jupiter; S = Saturn; U = Uranus.

We reprint from *Science* the following paper by Mr. J. Norman Lockyer:—

In order to obtain the greatest amount of assistance from observations of the eclipsed sun, it is necessary to consider in the most general way the condition of solar inquiry at the time the observations are made. If any special work commends itself to those interested in the problem,—work which may be likely to enable us to emphasise or reject existing ideas,—then that work should take precedence of all other.

Next, if the observers are sufficient in number to undertake other work besides this, then that work should be arranged in harmony with previous observations; that is, the old methods of work should be exactly followed, or they should be expanded so that a new series of observations may be begun in the light and in extension of the old ones.

In my opinion, and I only give it for what it is worth, the three burning questions at the present time—questions on which information is required in order that various forms of work may be undertaken to best advantage (besides eclipse-work)—are these:—

(1) The true constitution of the atmosphere of the sun. By this I mean, Are the various series of lines of the same element observed in sunspots, *e.g.*, limited to a certain stratum, each lower stratum being hotter, and therefore simpler in its spectrum, than the one overlying it? and do some of these strata, with their special spectra, exist high in the solar atmosphere, so that the Fraunhofer lines, represented in the spectrum of any one substance, are the result of an integration of the various absorptions from the highest stratum to the bottom one? This view is sharply opposed to the other, which affirms that the absorption of the Fraunhofer lines is due to one unique layer at the base of the atmosphere.

I pointed out before the eclipse of 1882 that crucial observations could be made during any eclipse, including the time both before and after totality. I made the observations: they entirely supported the first view, but I do not expect solar inquirers to throw overboard their own views until these observations of mine are confirmed; and I think one of the most important pieces of work to be done during the next eclipse is to see whether these observations can be depended upon or not.

One observer, I think, should repeat the work over the same limited region of the spectrum, near F; another observer should be told off to make similar observations in another part of the spectrum. I have prepared a map of the lines near E, for this purpose, showing those brightened on the passage from the arc to the spark, and those visible alone at the temperature of the oxy-hydrogen flame. Whereas some of the spark lines will be seen seven minutes before and after totality as short, bright lines, some of the others will be seen as thin, long lines just before and after totality. We want to know whether the lines seen at the temperature of the oxy-hydrogen flame will be seen at all, and, if so, to what height they extend.

(2) The second point to which I attach importance is one which can perhaps be left to a large extent to local observers, if the proper apparatus, which may cost very little, be taken out.

With this eclipse in view, I have for the last several months gone over all the recorded information, and have discussed the photographs taken at the various eclipses in connection with the spots observed, especially at those times.

The simple corona observed at a minimum with a considerable equatorial extension (twelve diameters, according to Langley), the complex corona observed at maximum when the spots have been located at latitudes less than 20°, have driven me to the view, which I shall expand on another occasion, that there is a flattened ring round the sun's equator, probably extending far beyond the true atmosphere; that in this ring are collected the products of condensation; and that it is from the surfaces of this ring chiefly that the fall of spot-forming material takes place.

If we take any streamer in mid-latitude, we find, that, while the spots may occur on the equatorial side of it, none are seen on the poleward side. I regard the streamers, therefore, like the metallic prominences, as a sequel to the spot; and there is evidence to suggest that a careful study will enable us to see by what process the reaction of the photosphere and underlying gases produced by the fall of spot-material tends to make the spot-material discharge itself in lower and lower latitudes, as the temperature of the sun's lower atmosphere gets enormously increased.

The observations of Profs. Newcomb and Langley at the minimum of 1878, on the equatorial extension, are among the most remarkable. Prof. Newcomb hid the

moon and 12′ of arc around it at the moment of totality by a disk of wood, carefully shielding his eyes before totality. Prof. Langley observed at a very considerable elevation. It is therefore quite easy to understand why this ring has not been seen or photographed at maximum. At maximum no precautions have been taken to shield the eye; no observations have been made at a considerable elevation; while the fact that the ring, if it exists, consists of cool material, fully explains how it is that the photographic plates have disregarded it.

I would propose, therefore, that the repetition of Prof. Newcomb's observations of 1878 be made an important part in the arrangements of the eclipse for this year. A slight alteration in the method will be necessary, as the ring will be near the vertex and the lowest point of the eclipsed sun.

(3) Another point of the highest importance at the present moment has relation to the existence of carbon. Until Tacchini's observations of 1883, the only trace of carbon in the solar spectrum consisted of ultra-violet flutings. He observed other flutings in the green near the streamers in the eclipse referred to.

Duner's recent work puts it beyond all doubt that stars of Class III. *b* have their visible absorption produced chiefly by carbon vapour.

On any theory of evolution, therefore, we must expect the sun's atmosphere to be composed to a large extent of carbon at some time or other; so that the highest interest attaches to this question in connection with the height in the atmosphere at which the evidence of carbon is observed. The existence of the ultra-violet flutings among the Fraunhofer lines tells nothing absolute about this height, although I inferred, at the time I made the announcement, that it existed at some height in the coronal atmosphere.

These three points, then, are those to which I attach special importance at the present time.

We next come to photographs of the corona. I believe, that, with our present knowledge, the chief thing we have to seek in such photographs is not merely the streamers and their outlines, which we are sure to get anyway, but images on a larger scale; so that in a series of short exposures we may endeavour to get some records which will eventually help us in determining the directions of the lower currents. At present we do not know absolutely whether these flow to or from the poles. My own impression is that the panaches at the poles indicate an upper outflow.

In coming to the photo-spectroscopic observations, I am of opinion, that of the two attacks which I first suggested for the eclipse of 1875, and which have also been used in the last two eclipses of 1882 and 1883, one of them should be discarded, and the whole effort concentrated on the other.

We have learned very much from the use of the prismatic camera,—one of the instruments referred to; but the results obtained by it are not of sufficient accuracy to enable them to be fully utilised. On the other hand, though the slit spectroscope failed in 1875, it succeeded with a brighter corona and more rapid plates in 1882; and, with a proper reference spectrum, every iota of the facts recorded can be at once utilised for laboratory work and subsequent discussion.

On these grounds, then, I would suggest that slit spectroscopes alone be used for photographic registration. I think falling plates should be used, and that the work should begin ten minutes before totality, and continue till ten minutes after; provided the slit be tangential, or nearly so, to the limb.

I may state that arrangements have been made here to take such a series of photographs on the uneclipsed sun; and, with the improved apparatus, I am greatly in hopes that we may get something worth having.

This paper was communicated to the Eclipse Committee, and formed in part the basis for the plan of operations on this occasion, which, as approved by the Committee, are as follows:—

Coronagraph before and after totality.. / Camera and prismatic camera during totality	Capt. Darwin
Camera and slit spectroscopes ... .. / Integrated intensity of corona	Capt. Abney
Camera and slit spectroscopes	Dr. Schuster
,, ,, ,,	Mr. Maunder
Observations of chromosphere before and after totality, and search for carbon bands during totality	Rev. S. J. Perry
Observations of chromosphere before and after totality, and direction of solar currents during totality	Mr. Turner
Images of corona on large and small scale (2 inches and ¾ inch) with photoheliograph and a 6-inch object-glass by Henry	Mr. Lockyer

Prof. Thorpe replaces Capt. Abney in the above list, and Prof. Tacchini joins the expedition at the invitation of the Royal Society.

NOTES

We regret to learn of the death of Dr. Abich, the eminent Russian geologist.

Mr. David Stephenson, of Edinburgh, the well-known civil engineer, died at North Berwick on Saturday last. He was born in 1815, and was a son of Mr. Robert Stephenson, the celebrated engineer of the Bell Rock and other lighthouses. His abilities in his profession were soon recognised. He was appointed at an early age engineer to the Lighthouse Board, and while occupying that position he constructed a number of important lighthouses. In the course of his career he held the office of consulting engineer to the Highland and Agricultural Society and to the Convention of the Royal Burghs, as also engineer to the Board of Fisheries and the Clyde Lighthouse Trust. Mr. Stephenson was a voluminous writer; his more important works included "A Sketch of Civil Engineering in North America," "The Application of Modern Hydrometry to the Practice of Civil Engineering," "Reclamation and Production of Agricultural Land," and "Principles and Practice of Canal and River Engineering." He was an occasional contributor to the columns of Nature.

The death is announced of Mr. Charles Mano, seven days after leaving Colon for France, at the age of fifty-five. M. Mano had made various journeys in Spanish America for scientific purposes. In Mexico he discovered several ancient cities which had never before been seen by any European. He was the scientific Commissioner of the Governments of Colombia and of Guatemala.

The arrangements for the Brighton meeting of the British Medical Association on the 10th, 11th, 12th, and 13th proximo are rapidly approaching completion. In the section of pathology, the new science of bacteriology will receive a good deal of attention, and microscopic photographs of these mysterious organisms will be shown by Dr. Heneage Gibbes and Dr. Crookshank, while the latter will also exhibit the various organisms growing in gelatine, &c.

We learn from the *Sidereal Messenger* for July that the contract for mounting the 36-inch objective has been awarded by the Lick trustees to Warner and Swasey, of Cleveland, O., for 42,000 dols. The telescope is to be 57 feet long; the diameter of the tube 42 inches. Provisions are made by which it will be possible for the observer at the eye-end of the telescope to command all the possible motions, and these same motions can also be controlled by an observer stationed on a small balcony

20 feet above the floor. It is expected that the mounting will be completed in April 1887, and that the glass will be brought to Mount Hamilton and put in place some time during the summer following. The total cost of the equatorial and dome will will be about 164,850 dols.; the cost of the dome being 56,850 dols.; the mounting, 42,000 dols.; the visual objective, 53,000 dols.; the additional photographic lens, 13,000 dols.

We have received a copy of the address of Sir William Manning, as Chancellor of the University of Sydney, at the annual commemoration. The report which it contains is one of progress in almost every direction. The death of Prof. Smith, who had long held the Chair of Experimental Physics, led to a re-arrangement of duties, a Professorship of Physics being substituted, with a wider and different range of teaching in Physical Science, including portions of the duties before discharged by the Professor of Mathematics as Professor also of Natural Philosophy. The list of private benefactions appended to the address is a remarkable one. It amounts to 317,414*l.* 12*s.* 6*d.* Of this, one amount, the Challis Bequest, is estimated at 180,000*l.*, and is anticipated to reach about 200,000*l.* As this noble donation has only recently fallen into possession, its application has not yet been fixed; the only point determined about it is that no part of it shall be used on buildings of any kind, but the capital shall be kept intact to produce an income for direct educational purposes. Another highly important gift is the Macleay Natural History Collection, valued at 25,000*l.* A building has been erected to receive the collection, and an endowment of 6000*l.* for a Curator has been promised. The other gifts include one of 30,000*l.* for the library. The amount of the donations since 1879 exceed a quarter of a million sterling—a magnificent sum for any community, however wealthy, to contribute in a few years to a single educational institution.

On Thursday last week the Photographic Exhibition, promoted by the Glasgow Town Council, was opened in the Corporation Galleries with a numerously attended *conversazione.* It is the fullest exposition, historical, practical, and scientific, of the art of photography which has yet been given. By means of an admirable series of examples it illustrates the development of photography from the earliest attempts of Wedgewood, Niepce, Daguerre, Fox-Talbot, and numerous other discoverers, to the latest products of those who are acknowledged at the present day as masters of the art. In the department of photo-lithography the numerous methods of photo-engraving and phototype-printing are fully represented by means of exhibits from the principal workers in that line. One of the most interesting sections is that which illustrates the applications of photography to the various branches of science, divided into its relations to geography, ethnology, microscopy, meteorology, and astronomy. In the last of these, the greatest of the recent triumphs in celestial photography by the Brothers Henry, of the Paris Observatory, are admirably shown; and there are also splendid examples of a similar kind from the Royal Observatory, as well as from Mr. A. Ainslie Common and others eminent in that field. The apparatus range from the primitive appliances of Daguerre to the latest ones of Messrs. Mason and Co., Glasgow; Mr. Stanley, London; and Mr. Marion, of the same city. Mr. James Paton, the curator of the galleries, has superintended the arrangements for the exhibition, which are of a most satisfactory nature.

We regret to learn of the probable early recall of the Commissioner of the Philippine Forest Department, and the practical suspension of the work in which he is engaged. The step is much to be regretted on many grounds, and it is to be hoped the Spanish Government will re-consider its decision in the matter. Until recently our knowledge of Philippine vegetation was extremely scanty, notwithstanding the collections made by the late Mr. Hugh Cuming. Even these it remained for Don Sebastian Vidal, Commissioner of Forests there, to place in accessible form, the materials for his recently-published "Phanerogamæ Cumingianæ Philippinarum" having been collected whilst engaged in working up his collections at Kew some two or three years ago. The extensive collections recently made by the Forest Department, a portion of which has been transmitted to Kew for determination, has, we believe, yielded a considerable proportion of novelties, including a number of genera not hitherto known from the islands. Information respecting these additions will probably be forthcoming in due course, as already we have an outline of the flora at the hands of one of the Kew staff. The above, together with the fact that the large island of Mindanao, and several others, is practically unexplored, shows how much yet remains to be done in this direction. From an economic stand-point, and for the development of the natural resources of the islands, the work of the department is an important one. The demand for timber, owing to the exhaustion of the forests in various directions, is assuredly forcing the forestry question into the foreground. As an example of how little we know of the Philippine flora, we may mention the St. Ignatius's bean, of which until recently nothing was known beyond the fact that it finds its way into the markets of this country as a source of the deadly poison strychnine, and was said to be sold in the market at Manila. Now, we believe, the plant has been discovered, and information respecting it will doubtless be shortly forthcoming. Such matters as these naturally engage the attention of the Forest Department, and it will be a matter for sincere regret if the work so well begun should come to a sudden termination, just at a time when its importance is beginning to be realised.

A Philippine correspondent, writing on May 24 last, informs us that the great volcano, Mayon, in the south of the Island of Luzon, is in eruption. He remarks:—"I tried the ascent, and climbed to about 5000 feet, when incandescent stones and ashes obliged me to come quickly down. I crossed a patch of forest—*Litsea verticillata*, *Myrica vidaliana*, and *Vaccinium* abundant—half burnt and covered with ashes. The sight was magnificent, but not much botanical work to be done there. I never saw anything like it as a sublime scene of devastation; ashes and stones and smoke everywhere, and a fearful noise like heavy artillery all around." *Myrica vidaliana*, it may be remembered, was described only about a year ago, from specimens collected at this very spot. At present it has not been found elsewhere, though it probably exists on other volcanic peaks in the island.

The *Melbourne Argus* of June 11 gives some particulars of the eruption of Mount Tarawera, in New Zealand, which was briefly reported by telegram. The first news of the outbreak was received at Auckland from the telegraphist at Rotorua on the morning of June 10. He said:—"We have all passed a fearful night here. The earth has been in a continual quake since midnight. At 2.10 a.m. there was a heavy quake and a fearful roar, which made every one run out of their houses. A grand yet terrible sight for those so near as we were presented itself. Mount Tarawera, close to Lake Rotomahana, suddenly became an active volcano, belching out fire and lava to a great height. The eruption appears to have extended itself to several places southward. A dense mass of ashes came pouring down here at 4 a.m., accompanied by a suffocating smell as from the lower regions. An immense black cloud, which extended in a line from Tapeka to Pairoa Mountain, was one continued mass of electricity all night, and is still the same. The thunder-like roaring of three or four craters, the stench, and the continual quaking of the earth, had the effect of completely frightening people." Things became so threatening that the telegraphist deemed it prudent to abandon his post; but he afterwards returned. At Wairoa the schoolhouse was fired by the light-

ning and smothered in mud and stones, and two hotels were reduced to ruins. Twenty bodies were recovered. For about six miles north of Te Awamutu the whole of the surrounding country was covered with blue mud 3 feet deep. It was reported that all Rotomahana had disappeared. Many natives lost their lives; but the exact number is not known. The sounds of the explosion were heard at Hamilton, about eighty miles distant, early in the morning. They were like great guns at sea. The windows of houses in Hamilton were shaken. At Maketu there was darkness until 10 a.m. The earthquakes lasted from 2.30 a.m. till 8.15, with very strong lightning and earth-currents. Four volcanoes were going at Wairoa. The Tikitapu bush has been uprooted. All the country down to Tauranga was in total darkness, with thick clouds of sulphurous matter and gypsum in the air. The following description of the scene was given in a message from Taupo:—"At 3 a.m. a terrific report aroused the sleeping inhabitants of Taupo, when an immense glare of a pillar-shaped light was observed to the north-north-east. A great black cloud hung over this pillar, concave on the under-side, and convex on the upper, whilst meteors on all sides shot out from the cloud in every direction, shedding an unearthly bluish light. Loud reports, accompanied by very heavy shocks of earthquake, followed in quick succession, and kept on until 6 o'clock, when the daylight and the clouds of ashes rendered the sight invisible. At 2.15 a.m. the two extinct volcanoes of Ruawhai and Tarawera threw an immense column of flame and smoke into the heavens. Molten lava and hot mud were rained abroad, while huge rocks and masses of fire went up and around in all directions. The earthquakes were terrible. Tongariro is quiet. Heavy snow is falling on the ranges and the cold is intense. The rumbling still continues at Maketu, and dust is still falling. The whole country is covered from 1 to 6 inches with dust."

THE series of anthropoid apes at the Zoological Society's Gardens at the present time is well worthy of attention. Besides "Sally," the bald-headed chimpanzee (*Anthropopithecus calvus*), which has now been two years in the Regent's Park, there is a second chimpanzee of the ordinary species (*A. troglodytes*), which enables these two forms to be compared side by side. A young orang (*Simia satyrus*) has likewise recently arrived, and a white-handed gibbon (*Hylobates lar*), from Malacca, deposited by Mr. Dudley Hervey, Resident Councillor of the Straits Settlements, exemplifies the third type of the highest division of the Quadrumana. It is much to be wished that the long-talked-of plan of building a new compartment by the side of the existing monkey-house for the Anthropoids could be carried out. At present these highly interesting animals are not very conveniently lodged along with the sloths and ant-eaters, on the other side of the Gardens.

THE half-yearly general meeting of the Scottish Meteorological Society will be held to-day, when the following papers will be read:—"The Extent of the Areas of the different Mean Annual Rainfalls over the Globe," by Mr. John Murray; "On the Temperature of the Water in the Firth of Clyde and connected Lochs," by Dr. Hugh Robert Mill, F.R.S.E.

MR. FRANK E. BEDDARD, Prosector of the Zoological Society, has been appointed Lecturer on Biology at Guy's Hospital.

ACCORDING to the programme of the approaching celebration of the 500th anniversary of the foundation of Heidelberg University, a grand historical procession designed and to be personally directed by Prof. Carl Hoff, of the Karlsruhe School of Art, will march through the town on August 6, starting at 9 a.m. More than 900 persons with 300 horses and 14 state coaches will take part in the procession, which is to give a pictorial representation of the five centuries which have succeeded the foundation of the University, and to comprise the following groups:—(*a*) Founding of the University by Elector Ruprecht I., 1386; (*b*) public entry of Frederich the Conqueror after the battle of Seckenheim, 1462; (*c*) nurture of science and art by Elector Otto Heinrich, 1556–59; (*d*) life among the people of the Merry Palatinate at the end of the 16th century: procession illustrating the vintage of the Palatinate; (*e*) entry of the Elector Frederick V. with his consort, Elizabeth of England, June 17, 1613; (*f*) Bohemian Embassy, 1619; (*g*) time of the Thirty Years' War (1618–48), and of the War of the Orleans Succession (1688–97); (*h*) Elector Karl Ludwig, with retinue, 1632–80; (*i*) time of the Elector Karl Philipp, 1716–42: hunting cavalcade; (*k*) Elector Karl Theodor, 1742–99; (*l*) Restoration of the University by Karl Friedrich of Baden, 1803: the students of the nineteenth century; (*m*) the Burschenschaften; (*n*) the Corps; (*o*) the new German Empire. Judging by the arrangements now nearly completed, the procession may be expected to surpass all previous exhibitions of the kind in the splendour of its equipage and the historical truth of its representation, which will be carried into even its minutest details. For the sake of a proper view of the procession, stands are to be erected at all convenient points along the line of the procession, and the sale of tickets for the numbered seats of the stands has already begun. A plan of the procession, issued by the firm Koester, Heidelberg, (price 20 Pfennige) shows the arrangement of the stands, with the prices of the various seats, and gives information respecting hotel accommodation, &c. A very considerable number of lodgings, we learn, have already been engaged by strangers intending to be present at the ceremonies connected with the celebration. All intending visitors who have not yet secured accommodation in respect of board and lodging are invited to make early application to the Commission specially appointed for the negotiation of such business—Wohnungs Commission, Rathhaus, Heidelberg. Beds are still to be had at the moderate price of 15 marks for the whole term of the celebration, while hotel-keepers, &c., have publicly engaged to keep their prices within strictly reasonable limits.

AT the Conference of the Colonial and Indian Exhibition, held on the 30th ult., Prof. Fream read a paper on "Colonial Forestry," dealing with the present condition of forestry in the larger colonies. In Canada there is need of conservation and of tree-planting, and everything now seems ripe for the establishment of a department of forest conservancy in the Dominion. In New South Wales such a department is at work under the Ministry of Mines; in Victoria a considerable area is reserved, but even this is not commensurate with the demand for timber for industrial purposes. In South Australia, Queensland, and New Zealand, efficient forestry departments exist. In Australia and the Cape Colony, English forest trees are being successfully cultivated, and "in all the colonies the reckless waste and wanton destruction of former days have given place to wise systems of conservancy, such as are worthy of a tree-loving people."

A SERIES of photographic views from a balloon has been taken by M. Nadar, of Paris, whose father, twenty-five years ago, was the first to attempt photographing from a balloon, with only partial success. The stereotype plates of the views taken were presented to the Academy of Sciences at their meeting on July 12.

SEVERAL attempts have lately been made by the Marquis of Lorne to transmit live whitefish (*Coregonus albus*), which have been reared by the National Fish Culture Association, to the Isle of Mull, where his lordship is endeavouring to acclimatise this valuable American species. After several futile attempts two consignments of them have reached their destination in safety. Great difficulty attends the operation of removing white

fish from one place to another. The best carrier for removing them in is an ordinary carboy filled to the top with water. Not more than fifty specimens of yearling fish should be placed in one carrier. The autumn is the best time for transmitting them.

WE are informed by Mr. W. August Carter, of the Colonial and Indian Exhibition Fisheries Section, that a large specimen of a smooth hound, recently imported into the aquarium of the Exhibition from Brighton, gave birth last week to ten young ones, this species being viviparous. She did not deliver them simultaneously, but two at a time, at intervals of about twenty hours, occupying six days in yielding the entire number. All the young on appearing were perfectly formed, and resembled in every respect their matured congeners with the exception of the colour of the upper portion of the body and fins, which was white throughout instead of grey. Unfortunately nine expired shortly after birth, lacking the conditions necessary to their existence, such as deep water, where in their natural state they always repair for six months during their alevin stage. The remaining fish was devoured by its parent, which is in excellent condition and moves actively around the tank.

FROM the report of the Stockholm Observatory for the last year, we learn that during the year Prof. Gyldèn continued the calculations for the development of certain theories respecting the chief planets, and that they are so far advanced as to already embrace the terms of the first and second orders in relation to the masses pertaining to the theory for the system Jupiter-Saturn-Uranus. The Astronomer-Royal also continued his lectures on theoretical astronomy, chiefly supported by King Oscar, which were attended by several eminent foreign astronomers. Several well-known astronomers from Russia and Germany have also pursued their studies at the observatory during the year, two of whom, Drs. Shdanow and Harzer, of Pulkowa, having, as the result of the same, published important papers on the astronomical theory of perturbation. Three more parts of the work, "Astronomical Observations and Researches at the Stockholm Observatory," were issued during the year.

BEFORE adjourning this summer the Swedish Parliament granted a sum of 325*l*. towards the continuation of the *Acta Mathematica* during the ensuing financial year 1886-87.

WE have received Nos. 45–47 of the first part, 34–36 of the second part, of the well-known and valuable "Encyclopædia of Natural Sciences," now in course of publication by the house of Eduard Trewendt, of Breslau. The three numbers of the first part include the seventeenth number of the "Manual of Botany," containing the beginning of an important note by Prof. Oscar Drude, of Dresden, on "The Systematic and Geographical Arrangement of the Phanerogams," illustrated with finely executed drawings by the author, and a map. The two other numbers belong to the "Alphabetical Manual of Zoology, Anthropology, and Ethnology," advancing that work from "Kalunda" to "Landrace." Nos. 34 and 36 of the second part carry on the "Alphabetical Manual of Chemistry" from "Essigsäure" to "Furfurangruppe." Of special interest is the excellent work by Dr. R. Nietzki, of Basel, on "Organic Colouring Materials." The 35th number, again, brings us nearer to the conclusion of the "Alphabetical Manual of Mineralogy, Geology, and Palæontology," containing, as it does, palæontological contributions by Dr. Fr. Rolles—Trias System, Birds, Wanderings of Plants and Animals in the Course of Geological Epochs, Mollusks, and Worms, as also mineralogical contributions by the Editor. The few articles that still remain to be written on geology, interrupted by the sudden death of Prof. von Lasaulx, will be taken up by Prof. Hœrnes, of Graz, so that this "Handwörterbuch" will be completed in the course of this summer.

THE Prince of Monaco has left Lorinet with his yacht *Hirondelle* to prosecute the series of marine observations begun last year. The cruise will be made between Cape Finisterre and the English southern coast. Five hundred tubes have been prepared, and will be thrown on the sea. They will carry printed forms of the same kind described on a former occasion. Dredgings and thermometric readings will be made on the bottom of the sea.

THE administration of the Jardin des Plantes of Paris has organised an exhibition of the objects collected on the Congo by M. Savorgnan de Brazza.

THE Franco-Algerian telegraph system is being completed to Biskra, but the communication between Biskra and Tugurth and Dabila oasis, situated at a great distance to the south, is kept up by means of the optical telegraph, the sun being utilised in daytime, and at night electricity. The optical system will be always kept in operation, as it is apprehended that nomads might cut the wires.

THE Kazan Society of Naturalists has issued the fourteenth volume of their *Memoirs* (*Trudy*), which contains a very interesting paper, by MM. Stuckenberg and Vysotski, on the Stone Age at Kazan. The commencement of a museum of Stone Age implements at Kazan was made in 1877, and now it already has a first-rate collection, both in the number and variety o implements, and M. Zausailoff is publishing a beautiful atlas of drawings representing them. The paper of MM. Stuckenberg and Vysotski contains most interesting details as to the places where remains of man were found, illustrated by three maps. Three different terraces are seen in the valley of the Volga. The upper terrace, rising 50 to 150 feet above the second, consists of yellow-brownish sandy clay, covering layers of sand. It contains remains of mammoths and other extinct mammals. The second terrace is much more recent ; and it is on its surface, as well as on the slopes of the former, and sometimes on the surface of the third terrace, that the stone implements are found. The third terrace, which is still inundated by the Volga, was probably almost covered by its waters during the Stone Age. All implements found are Neolithic ; that is, they belong to what we should call the lacustrine period. As to the implements themselves, many of which are figured on the sixteen plates which accompany the paper, they have mostly been made of the local flint originating from the Permian deposits. A few are made of the Eocene sandstone which extends to the south of the Kazan Government ; and, finally, boulders of granite, diorite, gneiss, quartzite, and so on, have also been used for the fabrication of some of the hammers. Broken pottery, together with bones of horses, oxen, and pigs, accompany the stone implements.

M. PALMIERI, the director of the Vesuvian Observatory, has succeeded in exhibiting the negative electricity developed when steam is condensed by cold, and positive electricity liberated when evaporation takes place. A platinum shell is placed in communication with one of the plates of a condenser. The golden leaf is separated when a piece of ice is placed in the shell, and also when it is full of water if exposed to the rays of the sun. The electricity has been proved positive in the first instance, and negative in the second.

DURING the last few weeks great tracts of the fertile island of Seeland, in Denmark, have been devastated by maybugs, whole fields and meadows having been laid quite bare. Last year the damage done was very great, but this year it is far worse, being estimated at some 25,000*l*. The distress among farmers is in consequence very great.

A MIRAGE was observed at Algiers prior to the outbreak of the destructive thunderstorm which broke over the city on the 7th

inst. Cape Matifan appeared from Algiers close at hand with a sharply cut rock of granite at its extremity. The temperature was 43°·2 C. in the shade, showing that the air above the sea was very hot, and that the explanation of the phenomenon is to be found in the same causes as those determining a mirage in the Sahara. The lowering of the temperature was very rapid, falling as much as 2° C. at Bouzarcah Observatory. The 7th inst. was the hottest day that has yet been felt there this season. Lightning struck the Government barrack at Mustapha, and ignited piles of hay, inflicting damage to the extent of 4000*l*.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. F. W. Steward; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mrs. Collcutt; six Prairie Marmots (*Cynomys ludovicianus*) from North America, presented by Mr. F. J. Thompson; two Common Foxes (*Canis vulpes*) from Russia, presented by Mr. Harrison Cripps, F.R.C.P.; a Common Rhea (*Rhea americana*) from South America, presented by Mr. J. W. Bell; four Red-bellied Squirrels (*Sciurus variegatus*) from Trinidad, presented by Mr. R. J. Lichmere Guppy; two Peba Armadillos (*Tatusia peba*) from South America, presented by Mr. J. Clements; a Greater Black-backed Gull (*Larus marinus*), British, presented by Mr. Henry Stevens, M.D.; twenty-four Sand-Lizards (*Lacerta agilis*), a Slowworm (*Anguis fragilis*), a Common Snake (*Tropidonotus natrix*) from Germany, presented by Mr. S. Schaefer; two Sarus Cranes (*Grus antigone*) from North India, eight European Tree Frogs (*Hyla arborea*) from Germany, purchased; two Long-fronted Gerbilles (*Gerbillus longifrons*), an Elliot's Pheasant (*Phasianus ellioti*), a Bronze-winged Dove (*Phaps chalcoptera*), a Barred-shouldered Dove (*Geopelia humeralis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

SCHULHOF'S RESEARCHES ON THE ORBIT OF COMET 1873 VII. (COGGIA—WINNECKE).—The elements of Comet 1873 VII. bear a certain resemblance to those of Comet 1818 I., which was observed by Pons. Prof. Weiss asserts the identity of these two comets, and adopts sixty-two years as the most probable value of the period of revolution. In the *Bulletin Astronomique*, tome iii. p. 125 *et seq.* M. L. Schulhof has published a most exhaustive discussion of the orbit of Comet 1873 VII., and has gone into the question of its possible identity with 1818 I., as well as with 1457 I. (the observations of which by Toscanelli have recently been discussed by Prof. Celoria) in a most thorough manner. The opinion which he expresses, with some reserve, as the result of his investigations, is that the Comets 1873 VII. and 1818 I. are distinct bodies with a short period of revolution, having a common origin. The Comet 1457 I. is probably identical with 1873 VII., but it is also possible that the two comets, 1873 VII. and 1818 I. are fragments of 1457 I., which must have been a much more conspicuous object than either of them, to have been seen by Toscanelli and by the Chinese with the naked eye.

SOLAR ACTIVITY DURING THE FIRST HALF OF 1886.—The numbers and areas of sunspots have shown upon the whole a decided falling off during the past half-year as compared with the last six months of 1885, although no month of the present year has shown so low a daily average as December 1885. There has been, however, a steady increase in the number of days on which the sun's disk was free from spots, one side of the sun being, on the average, much less spotted than the other, causing an apparent short period in the variation of the spotted area, of about a synodic rotation of the sun in duration. The month in which the mean daily number of sunspots was least was February; that in which it was most was March. An exceedingly fine group was observed on May 8.

Prominences have shown fewer fluctuations in their numbers and size, but have been fully one-fourth less numerous on the average than in 1885.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *JULY* 25–31

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on July 25

Sun rises, 4h. 15m.; souths, 12h. 6m. 14·6s.; sets, 19h. 57m.; decl. on meridian, 19° 38′ N.: Sidereal Time at Sunset, 16h. 11m.

Moon (one day after Last Quarter) rises, 23h. 35m.*; souths, 6h. 39m.; sets, 13h. 54m.; decl. on meridian, 11° 23′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 50	13 46	20 42	10 6 N.
Venus	1 37	9 46	17 55	22 22 N.
Mars	10 59	16 35	22 11	5 18 S.
Jupiter	9 47	15 54	22 1	0 32 N.
Saturn	2 43	10 51	18 59	22 15 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

July	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
27	85 Tauri	6	0 4	0 49	90 224
27	σ^2 Tauri	5	3 6	3 43	10 297
27	σ^1 Tauri	$5\frac{1}{2}$	3 23	near approach	334 —

July	h.	
25	5	Mercury at greatest distance from the Sun.
28	22	Venus in conjunction with and 0° 6′ south of μ Geminorum.
28	23	Venus in conjunction with and 3° 46′ north of the Moon.

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.	
U Cephei	0 52·2	81 16 N.	July 28,	22 51	*m*

δ Cephei	22 24·9	57 50 N.	,, 25,	21 30	*M*

M signifies maximum; *m* minimum; m_2 secondary minimum.

Meteor Showers

The principal shower is that of the *Aquarids*, maximum July 28; radiant R.A. 340°, Decl. 13° S. Other showers are as follows:—The *Andromedes* (I.), R.A. 8°, Decl. 36° N.; near χ Persei, R.A. 32°, Decl. 53° N.; near β Ursæ Majoris, R.A. 165°, Decl. 53° N.; and near the Pole, R.A. 300°, Decl. 87° N.

ON LAYING THE DUST IN MINES

IN a paper recently contributed to the South Wales Institute of Engineers,[1] Mr. Archibald Hood, the President, says:—

"It was probably first suggested by Faraday and Lyell about the year 1845 that coal-dust was in some way inflammable. This idea was subsequently set forth by several French engineers, but all that was done previous to the year 1875 bears the same relation to subsequent demonstrations as the steam-engine of Hero of Alexandria bears to the steam-engine of the nineteenth century."

Assuming Mr. Hood's date to mark correctly the commencement of the real battle between the new theory and its predecessors, it cannot surely be urged that the period of ten years which has since elapsed has been too long wherein to destroy the vast herd of previously existing chimeras, and to introduce and establish a new and different order of ideas. Doubtless the result attained up to the present has been prodigiously accelerated by the labours of the Royal Commission on Accidents in Mines, and of the

[1] "On the Watering of Dusty Mines." The South Wales Institute of Engineers, March 18, 1886.

similarly constituted bodies in France and Germany, all of which have been called into existence and have completed their labours within the period named. Indeed, scarcely had the ink with which the English Report was written been dry when the Home Office introduced a new Mines' Regulation Bill which provides, amongst other things, that "*In all dry and dusty mines the airways and travelling roads are to be kept clear of dust* OR *well watered, and a shot is not to be fired until the place and that near it is cleared of dust and then well watered*" ("*Mining Journal*").

The crudeness of the idea embodied in the first alternative, which appears to contemplate the possibility of removing the dust from roadways and airways without the simultaneous use of water, reminds one of an incident of the interview between Christian and the Interpreter ("Pilgrim's Progress"):—

"Then he took him by the hand and led him into a very large parlour that was full of dust because never swept; the which, after he had reviewed it a little while, the Interpreter called for a man to sweep. Now when he began to sweep the dust began so abundantly to fly about that Christian had almost therewith been choked. Then said the Interpreter to a damsel that stood by, 'Bring hither water and sprinkle the room,' the which, when she had done, it was swept and cleansed with pleasure."

It has all the appearance of being a compromise between efficiency on the one hand and ignorance or prejudice on the other, and closely resembles, in this respect, the first General Rule of the Act for the Regulation and Inspection of Mines, 1860 (23 and 24 Vic., cap. 151), according to which a mine was required to be ventilated only in such a way as to be safe *under ordinary circumstances*. But just as these qualifying words were found to be a cloak for all kinds of inefficiency in the matter of ventilation, and had to be ultimately expunged after a twelve years' trial, so we venture to predict will this other unscientific alternative, if passed into law, cause endless trouble and disaster, and require to be similarly dealt with at some future time.

To lay the dust sufficiently well to prevent the spread of an explosion requires a much smaller quantity of water than appears to be generally supposed.

This has been stated more or less directly several times in describing the results of coal-dust experiments; but it was very clearly brought out in the examination of the workings of Pochin Colliery, in Monmouthshire, after the great explosion in November 1884. The flame which in that case had all but filled the mine, and had penetrated into the remotest parts of three districts of workings ventilated by separate air-currents, was found to have been arrested by a slight dampness on one of the roadways leading to several working places. A cask conveying water from a dip place to a point more convenient to the pumps was hauled along this roadway four times every twenty-four hours, and it was stated by the manager of the colliery at the time that the dampness in question was due simply to accidental leakages from this cask and not to any intentional application of water for the purpose of laying the dust. At the inquest on Mardy explosion also, in January last, it was pointed out that a similar accidental or irregular system of watering appeared to have stopped the flame in four different directions, and to have saved the lives of many of the workmen (*Western Mail*, January 21, 1886).

Systematic watering with the avowed object of preventing the spread of explosions has hitherto been practised in very few collieries in this country. Llwynypia Colliery in the Rhondda Valley is a notable exception. Soon after the earliest coal-dust experiments had been made there in 1875 the intelligent proprietors and manager constructed a number of water-tanks on wheels, each provided with a perforated pipe at the back like an ordinary watering cart. Some of these were intended to be drawn by horses along the less frequented roadways, others to be attached to the trains of waggons which are drawn along the underground railways by means of wire ropes actuated by engine-power. The result of watering by this means was satisfactory and remarkable. The whole mine became cooler and more pleasant to live in. The dust, as such, disappeared not only from the floor of the roadways but also from the timbers and from the ledges formed by the irregular projections in the side-walls, and became consolidated into a firm, compact, and slightly humid mass under foot.

On their first arrival in this country in 1880, MM. Pernolet and Aguillon, who were sent by the Commission du Grisou to study the state of the English mines, expressed the opinion then generally held, that watering the floor of a dry mine would leave ample supplies of dust on the timbers and side-walls to carry on an explosion once begun. But after seeing the actual results in Llwynypia Colliery with their own eyes they altered their views considerably, as will appear from the following extract from their Report, which describes this incident of their visit:—

"*Ainsi, à Llwynypia, où les chantiers se développent jusqu'à* 1500 *mètres du puits, et où l'extraction est de* 550 *tonnes par jour avec un seul poste, il suffit par jour de* 5 *wagons a'une capacité d'un demi-mètre cube, soit de* 4·500*m. d'eau. Nous avons pu constater que les galeries étaient partout très propres et l'atmosphère très épurée, bien que cette mine passât auparavant pour une de cells où l'atmosphère était le plus chargée et le boisage le plus recouvert de poussières.*"[1]

About a year and a half ago the Home Office began unexpectedly to prosecute the managers of a few widely separated mines in different parts of the country for firing blasting shots while the men ordinarily employed were underground. The practice of blasting under these conditions had been going on unchallenged ever since the passing of the Coal Mines' Regulation Act, 1872, and it was with a feeling somewhat akin to consternation that the colliery owners viewed the new reading then for the first time seriously sought to be attached to part of one of the General Rules. The manager of the Standard Steam Coal Colliery in South Wales was selected out of hundreds of others in the same predicament, and a prosecution against him was begun. The colliery owners of the district rallied round the Monmouthshire and South Wales Collieries' Association, and undertook the defence. Happily, however, for the ends of justice, as well perhaps as for the cause of science, the case soon became involved in a whirlpool of legal formalities from which, as far as present appearances go, it is little likely to escape until after the passing of the new Mines' Bill.

During the earlier stages of this prosecution the representatives and advisers of the owners met the Inspector of Mines for the district (the late Mr. T. E. Wales) and asked him to represent to the Home Office that they were prepared immediately to submit to a new rule compelling them to water their mines systematically if the objectionable interpretation of the shot-firing rule were withdrawn. At the same time they expressed the opinion that the rule they were themselves proposing would afford a real protection to the lives of the miners, and that the one they desired to be superseded had been founded upon a misapprehension of the true causes of explosions. This intelligent proposal was, however, allowed to fall to the ground, and the Juggernaut of office rolled on its ponderous and relentless course.

Where simple tanks on wheels are difficult or expensive to manipulate, they may be advantageously replaced by a system of pipes bringing water from the surface, or from a reservoir at a convenient height in the shaft, and distributing it at different points of the workings, in the form of a fine spray. This arrangement has been successfully applied both at Llwynypia and Standard Collieries. At the latter colliery the pressure of water at the bottom of the shaft is regulated to fifty pounds on the square inch. The water pipes, which are one inch and a half in diameter, lie on the floor at one side of the roadway, or are supported on timber as the case may be. At distances of fifty yards apart upright branch pipes rise vertically from the main to a height of about four feet, each provided with a leaden plug with one minute hole. The jets of water are directed horizontally across the roadway, and the spray is carried along in the air-current, moistening the floor, more or less, all the way from one jet to the next. The cost of first establishment is stated to be about 5*l.* per hundred yards, and the cost of maintenance to be almost *nil.*

If the dew-point of the air entering a mine were by any simple means raised to the normal temperature of the strata in which the workings are situated, it is obvious that no system of watering would be necessary, and that any desirable degree of dampness could be maintained in the roadways. The only objection to this method is, that it would necessitate raising the general temperature of all dry mines.

A slight dampness, such as that which prevails in shallow mines at all times, is sufficient to lay the dust effectually; and it is highly probable that, so soon as anything approaching this condition is maintained also in deep mines, we shall have heard the very last of "Great Colliery Explosions."

W. GALLOWAY

[1] P. 287, "Exploitation et Réglementation des Mines à Grisou en Belgique, en Angleterre et en Allemagne." Rapport de Mission fait à la Commission chargée de l'étude des moyens propres à prévenir les explosions de grisou dans les Houillères, par MM. A. Pernolet et L. Aguillon, "Angleterre." Paris, 1881.

THE SUN AND STARS[1]

IX.

LET us consider the case, then, on the supposition of small masses of matter. Where are we to find them? The answer is easy;—in those small meteoric masses which an ever-increasing mass of evidence tends to show occupy all the realms of space.

In connection with this, perhaps I may be permitted to quote the following from one of my "Manchester Lectures":—

"There is one point to which I think I may be permitted to draw your attention, although at present it rests merely upon an unindorsed observation of my own. I thought it would be worth while to try what would happen if I inclosed specimens of meteorites, taken at random, in a tube from which I subsequently exhausted the air by a pump. After the pumping had gone on for some considerable time, of course we got an approach to a vacuum; and arrangements were made by means of which an electric spark could pass along this apparent vacuum, and give us the spectra of the gases evolved from the meteorites. Taking those precautions which are generally supposed to give us a spark of low temperature, and passing the current, we got a luminous effect which, on being analysed by the spectroscope, gave us that same spectrum of hydrocarbon which Mr. Huggins, Donati, and others have made us perfectly familiar with as the spectrum of the head of a comet. There, then, we get the atmosphere of meteorites, not necessarily carbonaceous meteorites, but meteorites taken at random; and this atmosphere is exactly what we get in the head of a comet.

"Now let me go one step further; and to take that step with advantage, allow me to refer to another point, . . . that whereas Schiaparelli has connected meteorites and falling stars with comets, Profs. Tait and Thomson, on the other hand, have connected comets with nebulæ, both of them being, according to those physicists, clouds of stones. Now how has one to carry these spectroscopic observations into the region of the nebulæ? A Leyden jar was included in the circuit, and we had what is generally supposed to be an electric current giving us a very much higher temperature than we had before. What, then, was the spectrum? The spectrum, so far as the known lines were concerned, was the spectrum which we get from the nebulæ; for the hydrocarbon[2] spectrum, which we get from the atmospheric meteorites at a low temperature, was replaced by the spectrum of hydrogen; the spectrum of hydrogen coming, of course, from the decomposition of the hydrocarbon, with the curious, but at present unexplained, fact that we got the spectrum indications of hydrogen without indications of carbon. In my laboratory work I have come across other curious cases in which compound vapours, when dissociated, only gave us one spectrum at a time—by which I mean that in a vapour consisting of two well-known substances, under one condition we only get the spectrum of one substance, and under another condition we get the spectrum of the other substance alone; so in others, again, of both combined. The evidence seems, therefore—though I do not profess to speak with certainty—entirely in favour of the ideas of Sir William Thomson and Prof. Tait on the one hand, and of Schiaparelli on the other."

I have given the above extract to show that a mass of meteorites at a temperature higher than that found to exist in a comet's head could give us the hydrogen spectrum which was discovered with such richness in the *Nova*, which is represented in the spectra of most nebulæ, and which remained in the spectra of the *Nova* after all the other lines had gone.

These considerations enhance the interest of the *Nova* to the spectroscopist if we accept the bright line observed in the star by Dr. Copeland and others to be veritably the chief nebula line.

This line brightened relatively with each decrease in the brilliancy of the hydrogen lines. On December 8, 1876, it was much fainter than F, while by March 2, 1877, F was a mere ghost by the side of it. On any probable supposition the temperature must have been higher at the former date.

Now it is well known that within certain limits the lines in the spectrum of a compound body get brighter with *decrease* of temperature, because at the higher one the compound almost entirely ceases to exist as such, and we get the lines of its constituents. It is a fair theory then to suggest that the famous nebula line may belong to a compound. Nay the fact as it stands alone further points to the possibility that the compound in question contains hydrogen as one of its constituents.

At present we know very little indeed about these new stars. The star which appeared last year in the nebula in Andromeda is, if possible, still more difficult to understand, because, although it was so near the centre of the nebula in apparent position, we do not know that it was near the nebula locally, or whether it was simply in the line of sight. Therefore the views with regard to that star are much complicated by the fact that it is uncertain whether it was associated with a nebula. It may have had nothing to do with it. I have received this morning from Paris a photograph taken by the Brothers Henry, who are working now at the Paris Observatory, recording the very interesting discovery that apparently growing out of the side of one of the stars of the Pleiades is a real nebula. Those of you who remember the photographs of the corona during different eclipses will imagine that there may be some connection between this star and the surrounding nebula. Now it seems certain that there is some connection between this star and the nebula, and it may be that, in fact, what we call nebula in this case is a very considerable expansion of the star's coronal atmosphere. So obvious is that suggestion, that I spent last night in trying to observe its spectrum. The fog was too much for me, but still, although there was very little light, it did look very much as if there were some bright lines in the bright part of the spectrum of the star. And if that is so, it will not only show you the possible connection of the nebula in Andromeda with the new star in Andromeda, but it also shows you the importance of the question of area which I brought before you in the previous part of the lecture, if the bright lines we got are due, not to the star itself, but to the incandescent area which surrounds it.

Finally, then, with regard to the new stars generally. That they are stars in our sense is, I think, quite impossible. Some of them, you know, lose their brilliancy in a very few weeks. Now we know that any body like the star which we are most familiar with—our sun—if ever it got to a sufficient degree of temperature to increase its light ten or twenty times, would not lose its temperature in ten or twenty days, or ten or twenty years, or ten or twenty thousand years, so that the more rapidly any of these bodies cool down, the less likely is it that the bodies which cool down have any considerable mass.

So obvious was that that on the appearance of the star in 1866 I made the suggestion, as I have said, that the body which gave us this light might be quite close to us. Well that was negatived. It was found that it was not—that it was at a stellar distance—that it was no more possible to tell its distance than it was that of an ordinary star.

We are driven then to the conclusion that, as we must account for a tremendous increase of light, and we know that this light was produced at a very great distance, and that one very large mass cannot be in question, we must distribute the light among a great many masses—the idea of a collision between two stars must give way to the idea of some action of a meteor-swarm in the case of a star already existing, like T Coronæ, and of a collision between two meteor-swarms in the case of a new one like that of 1876; that seems a possible explanation of a great many of these "stars"—the components of meteor-streams driven to incandescence supplying that light in consequence of the innumerable multitude of their components, the light dying out very quickly because these innumerable components are small and far apart.

The next order of variable stars to which I shall refer you is very well represented by β Lyræ. The curious point about this star is that it has a double minimum. Another star, η Argûs, with a bright line spectrum, is also remarkable from the fact that its maximum varies in the same sort of way.

In this star we get a number of differences. If you start from the maximum of the star you find it of three-and-a-quarter magnitude. It then in three-and-a-half days goes down to four-and-a-quarter. It then goes up so that in about six days it gets back again to its original brilliancy. It then goes down again, but does not stop where it did before, but goes half a magnitude lower, and then at last it ends the sequence of phenomena by getting up to its original brightness in thirteen days.

Now, although we cannot explain how it is, we have the fact that a curve of that kind is associated with a bright line spectrum. In η Argûs, one of the most remarkable stars in the heavens, we have very much the same conditions. This star is in the southern hemi-

[1] A Course of Lectures to Working Men delivered by J. Norman Lockyer, F.R.S., at the Museum of Practical Geology. Revised from shorthand notes. Continued from p. 230.

[2] The Lectures from which I am quoting were delivered many years ago, before the spectrum was recognised to belong to carbon.

sphere, and during the last twenty or thirty years a considerable discussion has been going on among astronomers as to whether the surrounding nebula is or is not changing its position with regard to the star. Now what happens to the star? I may tell you that the curve is only a rough one. But still you see the point fairly enough. This is, that this star, which has a bright line spectrum like β Lyræ, has a period not of thirteen days, but of seventy years. We find that the star, which is at first possibly below a sixth magnitude star, rises up to the first magnitude, but then goes down to the second, and so on. The curve shows a period of seventy years, the curve being very irregular.

The third and fourth classes, so far as we can see, resemble our sun. The curves suggest that of the sun's spot period, when we can make anything out of them at all.

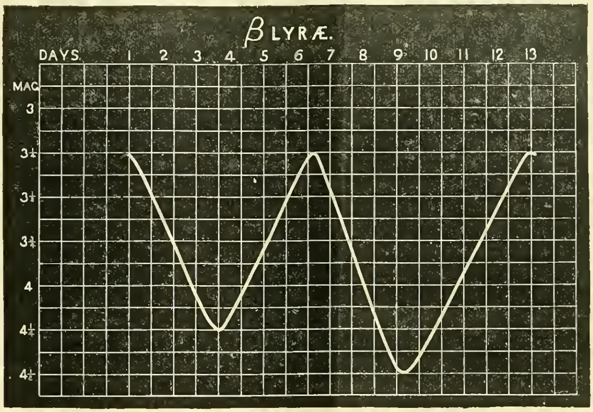

Fig. 27.—Light curve of β Lyræ.

But when we come to another class, in which we get a large light change in one period, there is one star, the history of which is so extraordinary that it is quite worth while to throw its light curve on the screen. It is called Mira, or the Marvellous. It is in the constellation of the Whale, and what happens to it in just a little less than a year is this. First it is of the second magnitude, and then in about eighty days it descends to the tenth magnitude, and then, so far as the observations have gone, it is invisible. In about another hundred days it again becomes visible as a star of the tenth magnitude. It then increases its light to the second magnitude, and begins the story over again. But sometimes at the maximum its brilliancy is not quite constant. That is to say, sometimes it goes nearer the first magnitude than the second. What happens to the light of the star below the tenth magnitude it is impossible to say. Whether it follows more nearly either of the dotted curves in the diagram is not known. Below the tenth magnitude no observations have been made, because it is very difficult to observe a star under those conditions. What one knows is that it remains invisible for about 140 days or something like that, and then it begins its cycle over again.

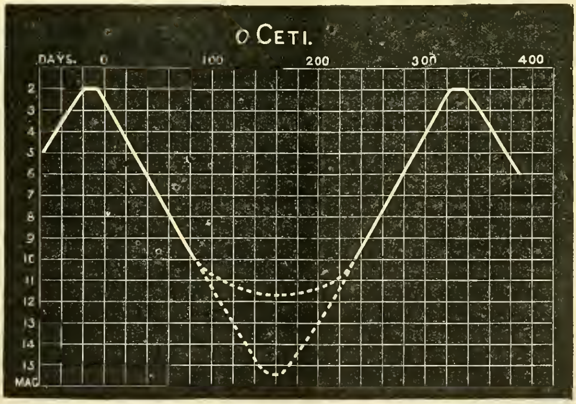

Fig. 28.—Light curve of Mira.

The next diagram illustrates the last conditions of variability,

the class of stars in which, if you remember, I told you that the variability probably did not depend upon the star itself, but upon its surroundings; and this is the famous star Algol, which is always visible in our latitudes. The history of the light changes of Algol is this. If we take the beginning of a cycle it is a star of the second magnitude. Suddenly in three hours it goes down to the fourth, and then it comes up in another three hours to the second, and goes on again for very nearly three days; and then it goes down again, comes up again, and goes on again for another three days, and so on. The diagram shows the exact

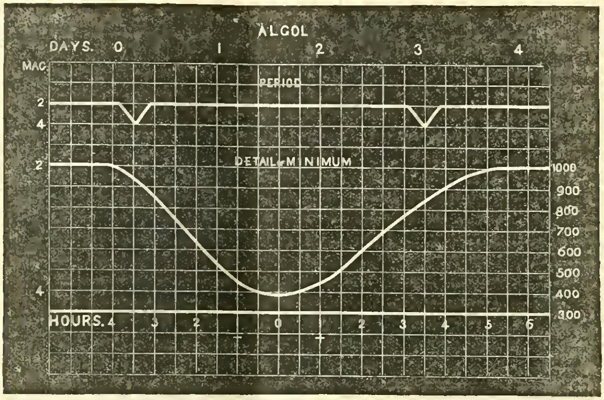

FIG. 29.—Light curve of Algol.

hape of the light curve as it has been determined by Prof. Pickering, dividing the light into a thousand parts.

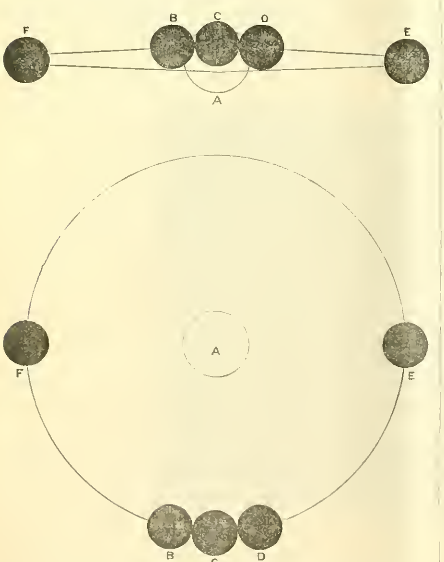

FIG. 30.—Plan and section of the orbit of the Companion of Algol.

There is another star very like this—a star which is in 81° N. declination, No. 25 in a well-known Catalogue. The difference between Algol and this is that the rise and fall are a little more rapid. Its light is feeble for about the same time as the other one, but at the bottom the curve is flat, by which I mean that, instead of going suddenly down and coming suddenly up again, it stops at its least luminosity for some little time.

Prof. Pickering has shown, I think, beyond all reasonable doubt that what is happening is this. If we take this diagram to represent in plan a large star giving out light, and B, C, D, E, F represent also in plan different positions of a dark body revolving round that central star; and then if you take the thing in section, so that the star and its satellite are represented as they really are in the plane which joins the earth and the star, you will see that in one part of the revolution of the dark body it eclipses the light body. Now, a further investigation of those conditions in the case of the second star has shown that there must be a total eclipse, and therefore Prof. Pickering draws the conclusion that in the former case the light of the body which revolves round the central one may be considered as *nil*—that is to say, that it is a dark body; but that in the case of the star D. 25—81° N.—there must be luminosity from the star which eclipses the other. And a very beautiful justification of that has recently been noted, because, although there is no change in the spectrum of Algol, there is a considerable change in the spectrum of that star the bottom curve of which is flat, showing that probably the companion has a large coronal atmosphere, and that the light of the central star has to pass through it. The light of the composite star practically changes from green to red very much as our sunlight would change if it had to pass through the atmosphere of another sun like itself coming between us.

I have prepared two or three other notes with regard to those special matters touching the stars which depend upon their distances, to show you that our sun, after all, is a small star—that there are several suns in the universe near enough to us to have had their distances already determined, which are considerably more brilliant and more imposing in every way than the star which is near us. But the clock tells me that I must leave all that to some other time, and I now end the course by thanking you very much for the indulgence that you have shown me in listening to what I have been able to tell you with regard to the constitution of our central body, and to the application of the knowledge which we have got in that way to an endeavour to cull some of the secrets of the physical construction of those suns which are very much farther removed from our ken.

J. NORMAN LOCKYER

SOCIETIES AND ACADEMIES

London

Physical Society, June 26.—Prof. W. E. Ayrton, F.R.S., Vice-President, in the chair.—Mr. E. M. Langley was elected a Member of the Society.—The following communications were read:—On certain sources of error in connection with experiments on torsional vibrations, by Mr. Herbert Tomlinson. During a long series of researches on the torsional elasticity and internal friction of metals, the author has come across the following sources of error in connection with torsional vibrations. In some of the earlier experiments a horizontal brass bar was suspended by a wire and oscillated, the times of oscillation being observed by the ordinary lamp, mirror, and scale. The moment of inertia was varied by sliding two brass cylinders, suspended from the bar by fine wires, backwards and forwards along it. It was then found that under certain conditions the bar executed a few vibrations of rapidly decreasing amplitude, came to rest, and then commenced to swing again, the amplitude increasing to a maximum, again decreasing, and so on. This effect was finally traced to an approach to synchronism between the time of oscillation of the bar and that of the small cylinders about their axes of suspension, the absorption of energy being due to these being set in vibration. The effect entirely disappeared upon clamping the cylinders rapidly to the bar. On another occasion, however, the old phenomenon reappeared, and after much time spent in investigating it, was found to be due to a somewhat similar cause, a near approach to synchronism between the periods of torsional and pendulous vibrations. If the axis of the wire passed accurately through the centre of mass of the vibrator, this would not occur; and this condition it is practically impossible to fulfil. Another source of error lies in the fact that, in a wire recently suspended, the torsional vibration-period will always be found to be slightly greater than when it has been suspended for some time and frequently oscillated.—On a mode of driving electric tuning-forks, by Prof. S. P. Thompson. It is invariably found that the frequency of an electrically maintained fork is continually changing. This great inconvenience the author believes to be due to the fact that the impulses are given to the prongs at a disadvantageous moment, namely, when they are at the extremities of their swings. It is desirable that the impulse should be given at the middle of the swing, and to effect this it is suggested that each fork should make and break the circuit of the magnet influencing the other one, and it was shown how the electrical connections could be made to effect this in a simple manner.—Prof. Silvanus P. Thompson then read some further notes on the formulæ of the electro-magnet and of the dynamo. The author pointed out that a misapprehension of his former paper on this subject had given rise to certain critical remarks by Dr. O. Fröhlich, to which he replied. The author also explained the new form given recently by Dr. Fröhlich to the formula of the electro-magnet, rendering it much more readily applicable to the various equations of dynamo-machines. Formerly the Lamont-Fröhlich formula had been written—

$$m = M \frac{kx}{1 + kx},$$

where M and k are constants, and x the magnetising force. Dr. Frohlich now suggested a formula of the form—

$$m = V \frac{x}{x + x'},$$

where V is the maximum value of m, and where x is either the current or the potential applied to the electro-magnet, and x' the diacritical value of the same; the "diacritical" value, as defined by the author in 1884, being that value which produced the state of half-saturation of the magnetic circuit. The author, folowing the lines laid down by Fröhlich in the use of this equation, showed that the general equation of the self-exciting dynamo is necessarily of the form

$$\psi = \Psi - \psi',$$

where ψ is either current or potential, ψ' the "diacritical" value of the same, and Ψ the "maximal" value of the same; that is to say, is the value which ψ would have if the given machine were run at the given speed and with the given internal and external resistances, but having its magnets independently excited to absolute saturation. Further deductions concerning the "dead turns" of the dynamo, their independence of speed, and dependence upon the resistances of the circuit and upon the construction of the machine were shown.

Sydney

Linnean Society of New South Wales, April 28.—Prof. W. J. Stephens, F.G.S., President, in the chair.—The following papers were read:—On some Lepidoptera from the Fly River, New Guinea, by E. Meyrick. Mr. Meyrick's paper contains an account of the Lepidoptera (Heterocera), collected by the recent New Guinea Expedition. Specimens of twenty-five species were met with, of which fifteen appear to be new, and are described by Mr. Meyrick. Nearly all of these may be said to be of normal Indo-Malayan types. A few specimens, from their bad condition, were unidentifiable or unfit for description.—Catalogue of the described Coleoptera of Australia, part 4, by George Masters. This part contains the names of, and references to, all the known species of the families—*Trixagidæ*, *Eucnemidæ*, *Elateridæ*, *Cebrionidæ*, *Rhipidoceridæ*, *Dascillidæ*, *Malacodermidæ*, *Cleridæ*, *Lymexylonidæ*, *Cupesidæ*, *Ptinidæ*, *Cioidæ*, *Bostrychidæ*, *Tenebrionidæ*, *Cistelidæ*, *Pythidæ*, *Monommatidæ*, *Melandryidæ*, *Lagriidæ*, *Pedilidæ*, *Anthicidæ*, *Pyrochroidæ*, *Mordellidæ*, *Rhipidophoridæ*, *Cantharidæ*, and *Œdemeridæ*, numbering 1494 species.—Miscellanea Entomologica, by William Macleay, F.L.S. This is the first of a series of papers descriptive of some of the new or rare Coleoptera in the Macleay Museum. The intention of the author is to accompany these descriptions with a general review of the genera or groups dealt with. The present paper is a revision of the genus *Diphucephala*, to which over twenty new species are added.—A revision of the Staphylinidæ of Australia, part 1, by A. Sidney Olliff, Assistant Zoologist, Australian Museum. The object of this paper is to furnish entomologists with descriptions of all the Australian Staphylinidæ at present known, to summarise the characters of the genera, and to make known a number of new forms. This first part contains the sub-family Aleocharinæ, of which the tribes Aleocharina, Gyrophænina, and Gymnusina are all represented. Among the most remarkable of the new forms belonging to the first of these tribes is a species from New South Wales described under the name *Apphiana veris* (gen. et sp. nov.), and characterised by having the basal joints of the antennæ enormously dilated on the outer side; the second joint being twice as broad as long, the third equally broad, but shorter, the fourth, fifth, and sixth shorter and gradually decreasing in breadth. In *facies* the species resembles a *Pelioptera*.—Notes from the Australian Museum, by E. P. Ramsay, F.R.S.E., and J. Douglas Ogilby. Two species of fish are described in this paper—*Myripristis carneus*, from the Admiralty Islands, presented to the Australian Museum by Capt. Farrell, and *Sygnathus parviceps*, from the Clarence River district, presented by Mr. Temperly, Inspector of Fisheries.—The Hon. James Norton exhibited a number of fossils (Chætetes and Spirifers) from Black Head, a few miles south of Kiama. Also, specimens of a porphyritic rock from Coolangatta, Shoalhaven, with the large crystals present in some, and decomposed by weathering in others.—Mr. Whitelegge exhibited specimens of a large species of *Nitella* with the following explanatory note. "A short time ago I found in the Parramatta River a very remarkable member of the above genus. It is an erect growing plant between 3 and 4 feet in height, mostly branching near the base, and giving off some five or six whorls of simple leaves, each leaf consisting usually of three cells, sometime of only two. The stem and leaves (six in number) are usually about $\frac{1}{16}$ of an inch in diameter. The internodal cells of the stem are usually 4 or 5 inches, but sometimes much longer. I have measured some of the largest yet found, and they are from 7 inches up to $8\frac{1}{2}$ long. It is highly probable that the cells of this plant are larger than those of any hitherto recorded. There are several other features which may not have been noticed in the genus. For instance, the leaves can be readily disarticulated from the stems without any apparent injury to either. When a cell is ruptured the sound produced is not unlike that of the bursting of the air-bladders of seaweeds. The rotation exhibited in the inner nodal cells differs from that of the stem and leaves, inasmuch as the chlorophyll granules take part in the general rotation. The protoplasm in the young leaves, when viewed under the microscope with the edge of the cell in focus, appears as a series of elevations and depressions, and with the higher part of the cell in focus, these elevations appear as clear spaces surrounded by small granules. Within the layer of protoplasm there exist large numbers of spherical clusters of needle-like

crystals, which circulate along the line of demarcation between the cell-sap and the protoplasm."

PARIS

Academy of Sciences, July 12.—M. Jurien de la Gravière, President, in the chair.—On the relations that exist between the geodetic and geological sciences, by M. Faye. The author's remarks are intended to show that the distinction formerly drawn between these two sciences can no longer be maintained. Thus in geodesy, for example, the sum of the forces acting on the terrestrial globe cannot be considered apart from those incessantly modifying its relief. The recent objection regarding the Quaternary glaciers is specially dealt with, not from the geological standpoint, but from that of the attraction exercised by them on the seas.—Note on the navigation of the Suez Canal at night, by M. de Lesseps. The question of nocturnal navigation, which would practically double the capacity of the canal, has now been studied exhaustively, and successfully solved by the adoption of signal lights along the route and electric lights on board the vessels in transit.—Experiments on waves, and especially on the diminution of the mean lateral pressures of undulations in canals, by M. A. de Caligny. A series of experiments are reported made on a miniature artificial canal, with the view of testing the various actions of translation and side pressure of the waves on floating bodies.—Reflections on the critical remarks of M. Hugoniot, which appeared in the *Comptes rendus* of June 28, by M. Hirn. The reference is to the author's last experiments on the flow of gases, some of whose conclusions are here sustained against M. Hirn's objections.—Identity of origin of the fluorescence $Z\beta$ by reversion, and of the bands obtained by Mr. Crookes in vacuum, by M. Lecoq de Boisbaudran. It is shown that the red band 619 of Mr. Crookes's former spectrum of yttria is due to the same earth as the author's band $Z\beta$ obtained by reversion, and that this band does not consequently characterise a new element.—Observations made during the cholera epidemic of 1885, by M. A. Guérard.—This work, by the engineer-in-chief of the Marseilles harbour works, traces the progress of the epidemic during the years 1884-85, and attributes its virulence primarily to the contaminated waters of the little River Huveaune used for domestic purposes in the districts which suffered most.—Observations of the new planet 259 and of the comet Brooks III., made at the Observatory of Nice (Gautier equatorial), by M. Charlois.—Solar observations during the first six months of the year 1886, by M. Tacchini. These observations show a progressive diminution of the phenomenon of solar spots, as well as of the solar protuberances.—On the Peruvian metrical standard, by M. Foerster. Admitting the authenticity of this standard, the author asks that accurate determinations be made of the value in metres of its two lengths, in order that all geodetic measurements, old and recent, be reduced to the same unity, that is, the international metre. In some subsequent remarks the same course was urged by M. Wolf.—Note on M. G. A. Hirn's experiments on the discharge of gases through orifices, by M. Parenty.—A new method of constructing the screw, by M. Trouvé. During the course of protracted experiments on the application of electricity to the propulsion of ships, the author has been led to study the various forms of screw now in use, and to devise another, here described, of far more simple structure.—On a physiological condition influencing photometric measurements, by M. Aug. Charpentier.—On the heat of formation of selenhydric acid, by M. Ch. Fabre. The three methods here described for measuring this heat of formation yield a mean of -9.44 cal. for gaseous selenhydric acid.—On a new species of asparagine, by M. A. Piutti. This new substance, recently discovered by the author while assisting at the preparation of asparagine in M. G. Parenti's laboratory, at Sienna, has a rotatory power, as determined by Laurent's great polarimeter, equal to, and with contrary sign to that of ordinary asparagine. The paper elicited some remarks by M. Pasteur on the great difference in taste of the two varieties of asparagine.—Distribution of a base between two acids; special case of the alkaline chromates, by M. P. Sabatier.—On the titanates of crystallised baryta and strontian, by M. L. Bourgeois. This paper is devoted to a study of the crystallised earthy alkaline titanates, which are obtained by the application of the known method—fusion of the elements of the salt in the corresponding chloride.—Action of chlorine on the seleniocyanate of potassium, by M. A. Verneuil. From the experiments here described, it appears that the action of chlorine on the alkaline seleniocyanates differs greatly from that which it exercises on the corresponding sulphocyanates. Bromine and iodine give rise to analogous phenomena.—Transformation of glucose to dextrine, by MM. E. Grimaux and L. Lefèvre. The transformation here effected for the first time is shown to throw some light on the somewhat obscure history of the dextrines.—On the transformation of the amides to amines, by M. H. Baubigny.—Isomery of the camphols and camphors; camphol of valerian, by M. Alb. Haller. A comparison of the properties of this camphol and its derivatives with those of the camphol of N'gai and its corresponding derivatives shows complete identity between these two products. In a further communication the author hopes to show that these two camphols themselves are also identical with that derived from the spirit of madder.—Electrolysis of an ammoniacal solution with the electrodes of carbon, by M. A. Millot.—On an alcoholate of crystallised potassa, by M. Engel. The body here determined, and named "alcoholate of potassa," has the formula—

$$KOH + 2(C_2H_6O).$$

—On propionic acid, by M. Ad. Renard.—Researches on the development of beetroot (continued); general conclusion; by M. Aimé Girard.—The law of connections applied to the morphology of the organs of the Mollusks, and especially of Ampullaria, by M. E. L. Bouvier.—On the presence of Ricins (Mallophages) in the quills of birds' feathers, by M. Trouessart.—On the absorption of carbonic acid by leaves, by MM. Dehérain and Maquenne. From the experiments here described it is shown (1) that the proportion of pure carbonic acid absorbed under atmospheric pressure varies with the quantity of water contained in the leaves; (2) that the coefficient of absorption of this acid by the water contained in the leaves is in the normal temperature superior to the coefficient of solubility of the same gas in water; (3) that the absorption is extremely rapid, which explains how the foliage is able to extract the extremely minute quantities of carbonic acid (some ten-thousandths) contained in the normal atmosphere.—On the crystallographic association of the triclinic felspars, by M. R. Bréon.—On the "ophite" eruptive rocks of Corbières, by M. Viguier.—Note on the primitive and Cambrian micaceous schists of Southern Andalusia, by MM. Ch. Barrois and Alb. Offret.—On injections of toxic gaseous medicines through the rectum; successful treatment of pulmonary affections by this means, by M. L. Bergeon.

THURSDAY, JULY 29, 1886

ELECTRIC TRANSMISSION OF ENERGY

Electric Transmission of Energy. By Gisbert Kapp, C.E. (London: Whittaker and Co., 1886.)

SINCE the invention of the electric telegraph the subject of the electric transmission of energy is that subject which of all others has most attracted the attention of practical scientific men. Under this head are comprehended every form of telegraph and of telephone, electric railways, and the electric transmission of power for the driving of lathes and other machines. Even the novel apparatus which has been described for enabling us to see what is happening at distant places and the very transmission of light itself through the interstellar ether must be regarded as parts of the great subject which Mr. Kapp has undertaken to treat of in this small volume. On examining the book, however, it will be found that the author has wisely confined his attention to the electric transmission of energy for the purpose of its being transformed at a distant place into mechanical energy for driving machinery. Indeed, it may be said that much more than half the book is devoted to the subject of the dynamo-machine, and that much less than half of it is devoted to the subject of the electric transmission of energy. Before electric energy can be transmitted it is necessary to produce it. It is rather difficult to imagine a store of electric energy existing anywhere and ready for transmission; and hence its production, transmission, and transformation into some other form of energy are circumstances which are exactly coincident with one another: as its transmission therefore implicitly involves its production and transformation, Mr. Kapp is perfectly justified in devoting as much of his book as he pleases to a description of the dynamo-machine.

Few people are better qualified to speak from experience of the most recent practice in the manufacture of dynamo-machines than the author of this book, and his paper entitled "Modern Continuous-Current Dynamo-Electric Machines and their Engines," read on November 24, 1885, before the Institution of Civil Engineers, and the discussion upon it, are to be regarded as exceedingly valuable helps to the electrical engineer. This book will be valuable to students who do not possess a copy of Mr. Kapp's original paper. It contains additional matter, much of it good; but to some of it we would offer a mild objection. For example, some distinction might have been made between the magnetic theories of Weber and Prof. Hughes. Mr. Kapp has certainly a good working knowledge of the theory of the dynamo-machine, and he leads up to the theory in a very ingenious way, but we are afraid that students will benefit more by reading an elementary treatise on electricity and magnetism, the writer of which may have had less originality than Mr. Kapp, than by taking their elementary notions from this book. Thus, for example, the following statement may have a perfectly orthodox meaning to Mr. Kapp:—"We can either assume that the lines are of different strength, and that the mechanical force with which a given free magnet pole is urged along any one particular line, is dependent on the strength of that line, which may be different from that of any other line belonging to the same field" (p. 18); but it will give great trouble to a student who knows that the resultant force is not the same at all points in a line of force, and who will find it inconsistent with the statements which Mr. Kapp has himself to make later on.

Again, we are disposed to think that it would be graceful in Mr. Kapp, and other makers of dynamo-machines at the present time, to give a little more credit to Gramme, and to refrain from dwelling so much on the great advances which have been made in recent years in the construction of dynamo-machines. When we compare modern machines with the Gramme machine of ten years ago, we see improvements on the original machine certainly, but they are very small. They consist mainly in ways of winding the conductor on the armature, so that it shall not readily slip or heat. How little of an essential kind has been introduced in the field-magnet arrangement may be gathered from the sheet of diagrams given at p. 102 of this book. In fact, a modern dynamo-machine may be said to be a Gramme or Siemens machine, the field-magnet circuit of which has been modified in a fanciful manner. Happily such modification in shape, however fanciful, does not seem to have impaired very much the efficiency of the arrangement, whereas it has enabled makers to greatly alter the outside appearances of machines, so that good Gramme and Siemens dynamo-machines are no longer called by these names, but by the names of the makers who have given them such various outside appearances. Large modern machines are superior to ancient small machines in efficiency and in the "output" per pound weight: firstly, because they are larger—and this is the main cause of their superiority; secondly, because the mechanical engineers to whom the details in construction have always been intrusted are now, some of them, slightly acquainted with the laws of electricity and magnetism; and, thirdly, because the manufacture of numerous machines has enabled costly manufacturing tools to be introduced, and these tools enable a method of construction to be employed which would in the past have been prohibited by the expense.

Again, we object somewhat to Mr. Kapp's use of the terms "theoretical" and "practical." For example, in discussing the efficiency of the electromotor when doing various amounts of work, at p. 129, he says that a certain statement which he has made is theoretically quite accurate, but from a practical point of view it requires some modification, and he proceeds to show that the want of accuracy was due to the fact that all considerations of magnetic and material friction had been neglected. We should have said in such a case that the statement was theoretically quite inaccurate. We consider that much mischief is occasionally done by what is usually called the comparison of theory and practice. If the mathematical results derived from some hypothesis which is evidently wrong be called a theory, we must of course have disagreement between theory and practice, and it is greatly in consequence of this that the majority of practical engineers have acquired a contempt for theory and for the reading of books which deal with the theoretical principles underlying their professional work. If the results of speculation on absurd hypotheses must be

compared with facts, the terms to be used are "hypothetical" and "practical."

This is one of three advertised books of "The Specialists' Series" which deal with electric engineering. Another of the three is devoted to the subject of magneto- and dynamo-electric machines, and the third is on electric lighting. We think it probable that in the greater part of Mr. Kapp's book he is going over ground which belongs almost altogether to the author of one of the other books of the series. As Mr. Kapp treats his subjects well, however, we cannot much object to this; but what we do object to is, that while taking up the subjects of the other authors, he has not given us his own subject. In sixty-three pages, or about one-fifth of the book, an instructive account is given of the various attempts which have been made to drive carriages on railways, telpher lines, ploughs, cranes, fans, and pumps, and we understand from Mr. Kapp's introduction that it is to this sort of transmission of energy that his book is devoted.

Now it is not merely sufficient for the author to give an account of what has already been done in this way; the reader expects a correct theoretical treatment of the whole subject, the cost of conductors, the fall of potential along the conductor, and the efficiency of transmission. These questions are sufficiently well taken up for a treatise on electric lighting, but for a book on the electric driving of machines at a distance the subject can hardly be said to be touched upon. Thus, for example, the development of Sir William Thomson's law as applied in electric light installations, and published by Prof. Forbes in his lectures at the Society of Arts, is carefully given. Now small alteration of potential difference at an incandescent lamp may produce disastrous effects on the lamp, may destroy it, or may cause sudden darkness, and this is the most important consideration in arranging conductors for lighting purposes; whereas, in the electric driving of trains or machinery, small alterations of potential difference are of no importance whatsoever. In consequence of this, in driving machinery electrically there may be a very considerable fall of potential along the conductor from the dynamo to the motor, and hence motors may be worked directly at distances which it would be absurd to contemplate in working an incandescent lamp. In fact the question of cost of conductors must be treated from quite a different point of view in the two cases, and it seems to us that Mr. Kapp has taken up the point of view which is most remote from his subject.

We think Mr. Kapp's book a very valuable addition to electrical engineering literature. It will be widely read, and it deserves the popularity which it will receive. Had we not thought it to be so excellent in many ways we should not have criticised it so narrowly, and, in spite of our warning to the student, we are very glad to meet with originality in leading up to the theory of the dynamo-machine. We are glad to see that the author has slightly amplified his account of the method, now in general use, of calculating the probable electromotive force of a dynamo-machine, which he published in his paper. The method is known to be practically correct, although it is based on a magnetic hypothesis of which there is no recognition in any book on physics—the hypothesis of magnetic resistance. We could have wished that Mr. Kapp had dwelt more upon this hypothesis, as we know of no actual results of experiment having yet been published which give it a general verification.

In reading over this criticism we feel that our objections to the book have all been brought very prominently forward. It would be very easy to point out here much that is good in the book, but perhaps our readers would then find this article long and tedious. Any reader of the book will find original and interesting views in every chapter; it is not every reader who would for himself have noticed the faults which we have here gathered together. We have achieved the difficult task of finding fault with an excellent book.

JOHN PERRY

OUR BOOK SHELF

The Aryan Maori. By Edward Tregear. (Wellington, N.Z.: George Didsbury, 1885.)

THIS little book contains a theory that the ancestors of the New Zealanders belonged to the Aryan race, and were a pastoral people. To signify this, the cover is adorned with a golden picture, seemingly representing a Maori warrior in native guise, accompanied by a sturdy little Highland bull. Now, it being notorious that the New Zealanders, when discovered, had no cattle nor remains of them in their country, the reader's curiosity is aroused to see how Mr. Edward Tregear supports this unlikely thesis. His method proves to be a philological paradox which we have never met with before. For example, it is argued (p. 31) that the Maoris once knew the bull by a word like the latin *taurus*, a bull. How so, one asks, when they no more had the word in their vocabulary than the beast on their land? The answer is, that in the absence of the word *taurus* itself the author relies on a dozen or so of other Maori words which he alleges to refer to it. The following are a few of them:—*Tara*, had courage; *tararau*, made a loud noise; *tararua*, had two points or peaks; *tareha*, was red; *tarehu*, caught one unawares; *tarore*, had a noose put on him; *taruke*, lay dead in numbers (if it was characteristic of the bulls to lie dead in numbers, how multitudinous the cows and calves must have been in the Aryan-Maori herds!). The poverty of the Maori language in consonants makes it easy to the author to play this fanciful game with his dictionary to his own full satisfaction. He takes a real interest in studying the Maoris, and though he has gone astray this time, he may, if a young man, do something more worth doing in the collection of native customs, legends, games, and the like which the older natives still remember.

LETTERS TO THE EDITOR

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Tidal Friction and the Evolution of a Satellite

IN NATURE, vol. xxxiii. p. 367, is an article by Mr. G. H. Darwin, defending his theory of tidal evolution, and dealing with what I have written respecting that theory. Space will here prevent my replying at length to the above; but as the author of it seems to think that my inquiry has been confined too much to the mode of origin of the moon, I have pushed it out in other directions, when important results have been obtained. I purpose here chiefly devoting my space to these, which can be put in a comparatively short and simple form.

But before entering on the new ground I think a few words of explanation will be necessary. Mr. Darwin takes exception to a proposition of mine in that it holds his theory to be dependent upon the genesis of the moon at the present surface of the earth. I was led to this conclusion chiefly from the apparent stress laid on the condition by the writer on that subject in Thomson and Tait's "Natural Philosophy," but as the author now states that his theory is not so founded, I think it ought to be allowed that it is not. But I think the argument can be put in another way; for if the moon be allowed to have separated at a period over four hours, the theory would be at variance with the calculations of its author (for he fixes the period at between two and four hours). A flock of meteorites is proposed as a form in which the moon might have receded from the earth. Nothing can be gained by this, for the flock of meteorites cannot come nearly so close to the earth as the moon in a single mass, without the constituent members being separated and each compelled to describe an independent orbit with its own period. In other words, the tidal force would separate the flock of meteorites at a greater distance than it would the single body. And at a greater distance it is not necessary, as the moon in her conglomerate form could not be objected to.

Also, he quotes and questions a passage, which is to the effect that two heavenly bodies cannot revolve about their centre of inertia with their surfaces nearly in contact, unless one is smaller than, and denser than, the other by a certain amount. The case was intended for where the two bodies move as parts of a rigid body, *i.e.* each keeps the same face towards the other; but I omitted to insert this condition in giving the rule.

Coming now to the results of my second investigation. In his last reply, as well as in several other places, Mr. Darwin advances the Martian system as affording a striking confirmation of the influence of tidal friction. The view is that the extreme minuteness of the inner satellite has preserved it as a standing memorial of the primitive time of rotation of Mars round his axis (see the *Observatory*, July, 1879).

Now I think it must have been taken for granted that the smallness of the satellite would allow the above state of things to come about, for an estimate of the comparative effects produced on Mars by solar and by satellite tidal friction, and the reaction on the satellite shows that, according to the estimated dimensions of the latter body, its period must be considerably more disturbed than that of Mars. Prof. Newcomb estimates the diameter of the inner satellite at from 10 to 40 miles. If we take the lower estimate and suppose the body to be only as dense as the sun, then its mass will be 86000^3 times smaller than the sun's. But the distance of the satellite—6000 miles—is 23333 times less than the sun's distance, and this number must be cubed to get the effect on the tidal force through greater proximity. After making the proper allowances, as above, it will be found that the satellite has a tidal force fifty times less than that of the sun. If the tidal retardation or acceleration, as the case may be, varies as the square of the tidal force, as Mr. Darwin allows, then 1/2500 of the planet's retardation must be counteracted by the satellite tides, which go round in the reverse direction to the solar tide. Here the reaction on the satellite must be considerable, for an approximate calculation will show that the orbital momentum of that body is only about 1/2,800,000 of the planet's rotational momentum. It will not be necessary to work out the calculation. Suffice it to say that the density and dimensions of the planet are taken from Newcomb's tables, and that the distribution of density is supposed to be like that of the earth, giving a rotational momentum equal to that of homogeneous density multiplied by 0·83.

If solar tides lengthen the Martian day by one minute, then the rotational momentum will have been reduced by about 1/1400 of the whole, and the satellite must have produced an effect in the opposite direction 2500 times as small, so that the actual effect of the satellite is to increase the rotational momentum by 1/3,500,000. And since the reaction on the satellite will be equal and in the opposite direction, more than half its momentum (which is 1/2,800,000 of the planet's) will be lost, which will reduce its distance to the surface of the planet. Hence we are led to the startling conclusion that before solar tidal friction can alter the rotation-period of Mars by one minute, the inner satellite must fall into the planet. I have not taken into the calculation the circumstance that the satellite tide goes round quicker than the solar one, nor that, as the satellite approached the planet, its tides would increase, the purpose here being only to give an account of the relative changes that should take place at about the present configuration. Further, it would seem that solar tides could not have reduced the period of Mars much, even if it be supposed that the inner satellite was first at any greater distance, for then it must either have gone out and attained a longer period than Mars, or it must have fallen into the central body long ere this. There seems no escape from these conclusions, unless the little body gives out an extraordinary amount of light for its size (for its probable size is judged by its brightness), but this seems so improbable, that it would be unreasonable to suppose so. As for the density, the inferior limit must be not less than half that allowed, otherwise the tidal force of the planet would break the body up.

Now a few words may be said on the future history of the moon. Before, I have said that the tracing back of the moon has apparently been carried too far in one direction; and now I think that the tracing forward, supposing tidal friction to have free play in the future, has been carried too far in the other direction. According to Thomson and Tait ("Elements of Natural Philosophy"), the moon's distance should increase to 347,100 miles by the time the earth's rotation relatively to the moon is stopped, when the two bodies should revolve in about 48·3 days. Now it would take all the rotative momentum that the earth would lose during the change to send the moon to the above distance; or, in other words, if there were no solar tides or other causes to prevent all the rotational momentum lost by the earth going to increase the moon's orbital momentum, the moon's distance would not be increased to beyond the above. But it is clear that a considerable portion of the rotative energy would be lost in solar tidal friction, which would have no part in increasing the moon's distance from the earth. For the moon to recede to the distance named, the earth must not only have its present moment of momentum, but also as much as solar tides would extract during the interval. At the present time the retardation through solar tides is not a small fraction of the whole, and it should increase till, at the other end of the journey, it will be more than half the whole retardation, for then the solar will be greater than the lunar tide.

I believe that Messrs. Darwin and Ball, who wrote a year or two before the date of Thomson and Tait's work, give the distance to which the moon will recede as even greater than the above, and say her period of revolution will be about fifty days. Certain remarks made by Mr. Darwin in the larger work of Thomson and Tait leave some doubt as to whether a correction has recently been made in the moment of momentum of the earth's rotation, but even if the earth be supposed homogeneous, the rotational momentum would not be sufficient to send the moon to the above distance, when allowance is made for solar tidal retardation. Hence it seems that no allowance has been made for the effects of this agency, and that when such allowance is made, the moon's destination must fall far short of the estimates given. If the distance (347,100 miles) be reduced to about 320,000 miles, I think it would be nearer the mark.

Mr. Darwin says that the eccentricity of the lunar orbit, the obliquity of the ecliptic, and other elements would be coordinated together by supposing that the moon first had a separate existence at no great distance from the present surface of the earth, and with small differential motion with respect thereto. I will only say that the case is so complicated, and the data so unreliable, that the results of the calculations involved seem to be little better than guess-work.

As for the distribution of satellites in the solar system, I think the majority of diverse theories would hold that they should be more numerous far from the sun, for the simple reason that solar disturbance would be less there. JAMES NOLAN

Dergholm, Victoria, May 25

MR. NOLAN is correct in supposing that I made no numerical calculation with regard to the inner satellites of Mars. I accept the calculation which he gives, and admit that the present period of revolution of the satellite cannot be regarded, as I supposed, as a memorial of the primitive period of rotation of the planet.

I see, however, no reason, as yet, to recede from the following statement (*Phil. Trans.*, Part II. 1880, p. 883), which embodies the essence of the argument, without the erroneous phrase:—

"It is here (in the case of Mars) alone in the whole system that we find a satellite moving orbitally faster than the planet rotates. This will also be the ultimate fate of our moon, because, after the moon's orbital motion has been reduced to

identity with that of the earth's rotation, solar tidal friction will further reduce the earth's angular velocity, the tidal reaction on the moon will be reversed, and the moon's orbital velocity will increase, and her distance from the earth will diminish. But since the moon's mass is very large, the moon must recede to an enormous distance from the earth, before this reversal will take place. Now the satellites of Mars are very small, and therefore they need only to recede a short distance from the planet before the reversal of tidal friction."

No one can have any datum for saying that the Martian satellite must have fallen into the planet "long ere this," but Mr. Nolan shows that the satellite is now near the end of its history.

I do not think that Sir William Thomson made any allowance for solar tidal friction in estimating the ultimate distance of the moon. Both he and I only cared to obtain the result in round numbers.

I should be very much obliged to Mr. Nolan if he would give a reference to the proof of the theorem, that two heavenly bodies cannot revolve about their centre of inertia, as parts of a rigid body with their surfaces nearly in contact, unless one is smaller and denser than the other by a certain amount.

July 15 G. H. Darwin

Peripatus in Demerara

Considering the great antiquity and importance of *Peripatus* it seems desirable to make a public notification of the fact that I have found a species, apparently *Peripatus Edwardsi*, in the Demerara division of British Guiana. Four specimens were obtained by me, but three of them, owing to some unknown cause, became considerably damaged and practically useless. The fourth specimen, which was found by me nearly a month ago, is still alive and evidently in good health. It is, when in progression, about $3\frac{1}{2}$ inches in length, but it often elongates itself considerably more and at other times becomes nearly coiled into a thick lump. It possesses thirty-one pairs of feet, the last three of which it rarely puts to the ground except when it goes backwards for short distances. Several other pairs at intervals along the body are carried off the ground in the same manner. It seems distinctly restless under the influence of light, appearing comfortable only when it retreats into some moist and darkened corner. When handled, it frequently discharges its viscid secretion, but as frequently neglects to do it when handled for the first time after a long interval, but more especially when touched or taken up for three or four times in rapid succession. It has been kept in an old sardine tin with small pieces of decayed wood, which were taken from the stump in which it was found, and the wood is kept in a moist condition. The locality from which it was obtained was the Hoorubea Creek, about twenty miles from Georgetown, on the east coast of the Demerara River, close to the meeting-point of an extensive forest and a water savannah. The four specimens were obtained in the same locality; and, though I have sought for them continually in other places, up to the present I have been unable to find others. From the long period of time during which this specimen has survived in confinement, I think there will be no difficulty, when I have obtained a large number of specimens, in sending them alive to England to Prof. Moseley and others. Unfortunately I have no possible access here to any literature on the group. I do not think it is generally known, but Mr. Im Thurn has once previously found specimens of Peripatus in the Essequebo division of British Guiana. His specimens were, however, very small ones.

British Guiana Museum John J. Quelch

Upper Wind-Currents over the Bay of Bengal in March, and Malaysia in April and May

In my last letter to Nature, vol. xxxiii. p. 460, on the subject of upper winds, I described the circulation of the Indian Ocean from the equator, where the north-west wind changes into the north-east monsoon, as far north as Ceylon, in the month of February. From there, about the beginning of March, I took a section of the weather, as nearly straight as practicable, from Colombo, through Calcutta, and 400 miles due north to Darjeeling.

The general weather system at that season is very simple. A belt of high pressure lies across the Bay of Bengal, from about Madras, to the southern limits of Burmah. The north-east monsoon blows to the south of this, towards the low pressure below the equator; the belt, of course, covers a calm area; while to the north a south-west wind blows towards a low pressure somewhere beyond the Himalayas.

The upper currents over the north-east monsoon always blew from some more easterly point than the surface-wind; the cloudless sky over Madras prevented any observations; north of this the higher clouds always came from some point more northerly than the south-west wind below. The lofty range of the Himalayas seemed to make no difference; at Sendukphu I succeeded in getting a photograph of a cumulo-form cloud trailing from the summit of Kanching Junga (29,000 feet) well from the west-north-west, while a south-west wind was driving up mist from the plains. The existence of cumulus at so high a level has, I think, been denied by some meteorologists.

All these observations are in complete accordance with the normal circulation of the northern hemisphere; but the character of south-west monsoons deserves notice. The term south-west monsoon is unfortunately used for two different stages of the same weather sequence, and much confusion comes thereby. Maury and others think only of the direction of the wind; common parlance all over the East talks of the monsoon as of a rainy season which sets in suddenly, long after south-west winds have been blowing for weeks or months previously.

The facts of the case are these:—As early as January a light south-west wind commences in the north of the Bay of Bengal, first only as a sea breeze; later, when we encountered it, as a light continuous wind. Nothing can be more lovely than the weather then; bright blue sky, scarcely a light cloud, with a warm gentle wind; the monsoon, unlike March, begins like a lamb and goes out like a lion. As the season goes on an area of low pressure, which has been gradually forming over Northern Bengal, becomes more pronounced, and the south-west wind gradually works further and further to the southwards below Ceylon. Then, sometimes in June, a sudden total change comes over the weather, while the only alteration the isobars show is a slight motion of the lowest pressure towards the North-west Provinces of India. A sudden burst of rain and thunder breaks over Ceylon, and then the bad weather works slowly northwards. This is the commencement of the south-west monsoon in common talk. Everyone will tell you how many days it takes to work up to Bombay on one side and to Calcutta, by way of Burmah and Assam, on the other. Madras escapes for the present, only to be deluged in November by the north-east monsoon. So we get the curious sequence that the wind works downwards, the rain upwards; and also the fact that the greatest and most sudden change in the year is associated with no striking change in the distribution of pressure. The Indian meteorologists are of opinion that this sudden change in the character of the same wind is due to a sudden irruption of air, highly charged with vapour from the neighbourhood of the equatorial doldrums, but that the south-east trade is not linked with the south-west monsoon in a continuous current, except occasionally and temporarily. Would it not be of the highest interest and importance to discover whether this sudden change of weather is associated with any change in the relation of the upper and lower winds? In my letter to Nature (vol. xxxiii. p. 460) I showed that over the south-west monsoon of the Gulf of Guinea the upper currents were those of the southern hemisphere, and that the south-east trade there seemed to grow gradually into a south-west wind as it crossed the line. If in Ceylon and India the higher clouds continue to come, as we found them, from west or north-west after the burst of the south-west monsoon, there must be a doldrum between it and the south-east trade; but if the upper currents turn towards south or south-east after the burst, then undoubtedly the south-east trade has invaded the northern hemisphere. The latter is of course the old theory of the monsoon; and perhaps another test may be applied to the solution of these alternatives. If the south-east trade blows into a doldrum, there must be a belt of high pressure between Ceylon and the equator to give gradients for south-west winds. Has this ever been found? I do not think that calm alone is sufficient to be called a "doldrum." During the north-west monsoon, which is unquestionably the north-east monsoon drawn across the line, the direction of the wind changes gradually, but the velocity is often less just on the equator than on either side. I made some special inquiries on this point.

In the Philippines, China, and Japan the upper winds over the south-west monsoon follow the normal course of the northern hemisphere; but there is no burst of the monsoon in those countries.

Some meteorologists have asserted that the south-west monsoon may be considered a stationary cyclone. This might be so if we define a cyclone simply as an irregularly circular area of low pressure round and into which the wind blows spirally. But when we look at the kind of rain and varieties of cloud which give distinctive character to various parts of a cyclone, our own observations and the information we have received from others entirely discountenance this idea.

In Malaysia, between Singapore and Borneo, in the early days of April the surface-winds were all from about north-east, and the clouds at various levels always from more south of east. In North Borneo, later in the month, the south-west land breeze of the morning always went round by south-east to north-east in the afternoon and evening, while the higher clouds came always from about north-east.

In Sooloo and the Philippines during the month of May the surface winds were much complicated by land and sea breezes, but the sequence of upper currents was always that proper to the hemisphere.

So far for ordinary weather. I was not fortunate enough to meet with a typhoon, but the reports of the observatories at Manilla, Hong Kong, and Tokio are all agreed that the relation of upper and lower currents is the same in a typhoon in the China Seas as in a European cyclone.

Yokohama, June 12 RALPH ABERCROMBY

Mock Sun

I INCLOSE sketch of the first mock sun I have been fortunate enough to see at Cranbrook, Kent, on July 20, 5 to $5\frac{1}{2}$ p.m.

About 10m. before noticing this fine phenomenon we had noticed a fragment of it, not knowing what was to follow; and we were struck by the extraordinary position of the bow with reference to the sun, viz. about 45° from it, and at an unaccountable angle to the horizon. The latter picture I can only draw by memory. The upper drawing is from one made on the spot in presence of two intelligent adult witnesses, who were consulted on each point which I proceed to notice.

(1) The rainbow near the zenith was of the breadth and brilliancy of an ordinary rainbow (the same was the case with the fragment seen ten minutes earlier, which was lost when the rest came out). The fact of the arc seen near the zenith belonging to two circles, one small and one large, touching each other, was sufficiently certain to my eye, confirmed by another educated eye, but not admitted by the third less educated one. I draw it as I apprehended it. The colours were unusually vivid against a thin veil of fleecy clouds.

(2) The halo-circle round the sun, and the arched eyebrows, so to call them, were about half the breadth of the rainbow, and washy in colour. The shapes drawn are quite faithful, and were so sharp as to leave no room whatever for doubt or imagination.

(3) The interior area of the circle was darker than the ouside.

(4) The position of the mock sun was not diametrical. The sun, seen through a handkerchief whose edge was stretched through the two mocks, was about two-thirds of its own breadth below the edge, clear.

(5) The white rays (about half the breadth of the mock lights) were seldom seen both at the same time, but were quite decided outside the circle and traceable within it, but nowhere nearly so bright as the mock lights.

(6) The mock lights were short fragments of arcs of rainbows, more vividly coloured than the halo-circle outside of which they stood clear of it, but not so broad and not quite so vivid as the great rainbow arc.

These fragments were *not* tangential. Short as they were, their own axis was clearly determined by all three witnesses to be inclined towards the radial ray, and more inclined to the arc of the halo. But I have unconsciously given a curved shape to the short fragment. It was too short to show a curve. There was no pretence of a disk, as if really a mock sun. It was only a very vivid fragment of a rainbow. A third fainter one was at the top of the halo.

The sky was much covered with thin cirrus; a fine sunny evening; air peculiarly clear for distant views.

Collingwood, July 22 W. J. HERSCHEL

P.S.—Radius of halo-circle, measured as best I could, $22\frac{1}{2}° \pm 2\frac{1}{2}°$. Radius, continued to the rainbow, 45° with proportionate error. The arc of the halo-circle was generally absent next to the mock lights, but could sometimes be traced.

"The Duration of Germ-Life in Water"

IN a letter bearing this title in your last issue (p. 265) Mr. Downes refers to the recent publication by Messrs. Crookes, Odling, and Tidy, of some experiments which they have made on the vitality of the *Bacillus anthracis* in water, with regard to which I should like to call attention to the fact that this subject has during the past three years been investigated by various experimenters, including Koch, Cornil, and Babes, Nicati and Rietsch. Within the past two months no less than three papers have been published on this subject, two of them in Germany by Dr. Wolfhügel and Meade Bolton respectively, whilst the third, by myself, "On the Multiplication of Micro-organisms," was communicated to the Royal Society at the meeting in June last. In this paper I have recorded a number of experiments made both with the mixtures of organisms found in various natural waters, as well as with three well-characterised forms which are associated with disease, viz. Koch's "Comma" spirillum of Asiatic cholera, Finkler-Prior's "Comma" spirillum of European cholera, and the Bacillus pyocyaneus, which produces the greenish-blue colouring matter frequently present in abscesses. The methods of research which have been independently selected both by Wolfhügel, Meade Bolton, and myself, are identical, and consist in the examination, by gelatine plate-cultivation, of waters purposely impregnated with the organisms in question. This method is obviously the one which most recommends itself for the purpose, as it not only enables one to ascertain the presence or absence of the organisms, but also to quantitatively follow their multiplication or reduction. I may mention that these three organisms present great differences in their behaviour under similar circumstances; thus the *Bacillus pyocyaneus* is possessed of far greater vitality in water than either of the other two, its presence being demonstrable even in distilled water after fifty-three days, in numbers exceeding manyfold those originally introduced. Koch's "Comma' spirillum, on the other hand, was in the purest forms of potable water no longer demonstrable after the ninth day, whilst in London sewage it was found in largely multiplied numbers after twenty-nine days; whilst Finkler's spirillum could in no case be detected after the first day, and frequently not even on the day of inoculation. A curious phenomenon, which my experiments, as well as those of Wolfhügel and Meade Bolton have brought to light, is that when organisms of this kind, which are not the natural inhabitants of water, are introduced into this medium, a large proportion of them are frequently at first destroyed, a greater or less multiplication in their numbers often subsequently taking place.

The *Bacillus anthracis*, as is well known to bacteriologists, appears in two very distinct forms, the *bacillus*-form and the *spore*-form, and these present very great differences in their powers of endurance, the former being destroyed with comparative ease, whilst the spores are remarkable for their vitality. Mr. Crookes and his colleagues have apparently experimented with the bacillus-form of anthrax only, which they state is rapidly destroyed when introduced into London water, but Dr. Meade Bolton, who has dealt with anthrax in both its forms, has shown that the spores of anthrax retain their vitality even in distilled water for upwards of ninety days, and that it is only the bacilli which rapidly perish in some kinds of potable water. In polluted well-water Meade Bolton has also shown that even the bacilli are persistent for upwards of ninety days, and the spores for nearly a year, whilst Wolfhügel has found that in polluted river-water (the River Panke, in Berlin), even when diluted tenfold with distilled water, the anthrax bacilli undergo extensive multiplication. Normal School of Science,
South Kensington Museum, S.W., July 26

Animal Intelligence

IN NATURE for July 22, on p. 265, Mr. Frederick Lewis calls attention to a nest-building wasp who closed up her nest without filling it first with grubs or laying an egg. There is nothing uncommon in this neglect on the part of the wasp, as any one who has at all studied their habits in the tropics will know, such perfectly empty nests being frequently met with. I have often thought the empty nest might have something to do with the fact that the wasp may not have been prepared to deposit her egg; but then, if that were the case, we should occasionally find nests with the remains of the caterpillars or

spiders collected. When a wasp has once chosen a site for building, it is very difficult to drive her away.

63, St. George Street, Leeds HY. LING ROTH

The Microscope as a Refractor

I AM rather surprised, after the judicious remarks of Dr. Gladstone on this subject in NATURE of July 1 (p. 192), to find Mr. Gordon Thompson still maintaining his opinion to have introduced anything not yet known or tried with the microscope adapted to this purpose. If he had had time to go over the papers of Royston Pigott (*Proceedings* of the Royal Society, 1876), of Mr. Sorby (*Mineralogical Magazine*, 1878), and of myself (*Proceedings* of the Royal Society, 1884), he could have convinced himself that all what he proposes has been already elaborated and applied. He could also have learnt why the method with the microscope is limited in its exactitude to the third decimal, as the mathematical expression which it involves is deduced from not very strict principles, this being as well the case with the formula for the hollow prism.

The Hague, July 21 L. BLEEKRODE

HERRMANN ABICH

AS briefly reported in NATURE last week this venerable geologist died at Vienna on July 1. As far back as the year 1831 he began his scientific career by the publication of an important memoir, in which by novel methods of chemical analysis he determined the composition of various minerals of the Spinel family, and showed how alike by chemical composition and crystalline form they could all be ranged in one group. This early paper gave evidence of the carefulness of observation which distinguished him through life. It was followed by other chemical and mineralogical essays, especially in the department of volcanic products. Gradually he was led to devote special attention to the phenomena of volcanic action, and in the course of his investigations to visit most of the volcanic districts of Europe. His folio atlas of views illustrative of Vesuvius and Etna (1837), and his "Vulkanische Bildungen" (1841), are among the best known of his writings. He had great facility as a sketcher, and some of his drawings of volcanic craters have done duty for nearly half a century in text-books in many languages. The east of Europe presented a wide and almost unknown field for his exploration. As far back as 1840 he published notices of his wanderings in the Caucasus. He ascended to the summit of Mount Ararat, and devoted most of the remainder of his life to the investigation of the vast region of the Caucasus and south-eastern Europe. Many papers published from time to time in the scientific journals record his unwearied industry. But perhaps the most striking and durable monument of his scientific achievements is his great work, "Geologische Forschungen in den Kaukasischen Landern," the publication of which he was superintending at the time of his death. This magnificent monograph, of which only the first part has been published, brings before the reader in a series of maps, sketches, large panoramic views, and detailed descriptions a picture of the external aspect and geological structure of the Caucasian region and impresses him with a profound admiration for the author's geological prowess. Abich had during the last few years settled in Vienna, availing himself of the typographic facilities to be found in the Austrian capital. He has been a notable instance of the longevity attained by many active field-geologists, for he almost reached the age of three score and ten years, retaining to the end his enthusiasm and industry. It is to be hoped that the second part of his monumental work, which is to treat of the eastern half of the Armenian Highlands, has been left in such a state as to admit of publication.

CAPILLARY ATTRACTION[1]

II.

NOW in this second way we have, in performing the folding motion, allowed the water surface to become less by 60 square centimetres. It is easily seen that, provided the radius of curvature in every part of the surface exceeds one or two hundred times the extent of distance to which the molecular attraction is sensible, or, as we may say practically, provided the radius of curvature is everwhere greater than 5000 micro-millimetres (that is, the two-hundredth of a millimetre), we should have obtained this amount of work with the same diminution of water-surface, however performed. Hence our result is that we have found 4·5/60 (or 3/40) of a centimetre-gramme of work per square centimetre of diminution of surface. This is precisely the result we should have had if the water had been absolutely deprived of the attractive force between water and water, and its whole surface had been coated over with an infinitely thin contractile film possessing a uniform contractile force of 3/40 of a gramme weight, or 75 milligrammes, per lineal centimetre.

It is now convenient to keep to our ideal film, and give

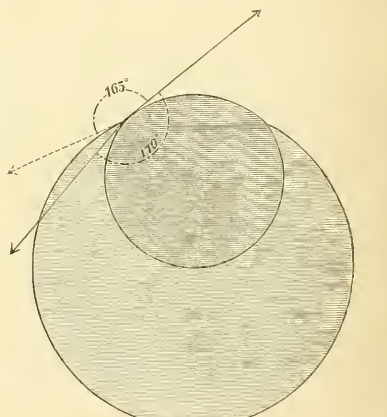

FIG. 2.

up thinking of what, according to our present capacity for imagining molecular action, is the more real thing—namely, the mutual attraction between the different portions of the liquid. But do not, I entreat you, fall into the paradoxical habit of thinking of the surface film as other than an ideal way of stating the resultant effect of mutual attraction between the different portions of the fluid. Look, now, at one of the pieces of water ideally rigidified, or, if you please, at the two pieces put together to make one. Remember we are at the centre of the earth. What will take place if this piece of matter resting in the air before you suddenly ceases to be rigid? Imagine it, as I have said, to be enclosed in a film everywhere tending to contract with a force equal to 3/40 of a gramme or 75 milligrammes weight per lineal centimetre. This contractile film will clearly press most where the convexity is greatest. A very elementary piece of mathematics tells us that on the rigid convex surface which you see, the amount of its pressure per square centimetre will be found by multiplying the sum[2] of the curvatures in two mutually-perpendicular normal sections

[1] Continued from p. 272.

[2] This sum for brevity I henceforth call simply "the curvature of the surface" at any point.

by the amount of the force per lineal centimetre. In any place where the surface is concave the effect of the surface tension is to suck outwards—that is to say, in mathematical language, to exert negative pressure inwards. Now, suppose in an instant the rigidity to be annulled, and the piece of glass which you see, still undisturbed by gravity, to become water. The instantaneous effect of these unequal pressures over its surface will be to set it in motion. If it were a perfect fluid it would go on vibrating for ever with wildly-irregular vibrations, starting from so rude an initial shape as this which I hold in my hand. Water, as any other liquid, is in reality viscous, and therefore the vibrations will gradually subside, and the piece of matter will come to rest in a spherical figure, slightly warmed as the result of the work done by the forces of mutual attraction by which it was set in motion from the initial shape. The work done by these forces during the change of the body from any one shape to any other is in simple proportion to the diminution of the whole surface area; and the configuration of equilibrium, when there is no disturbance from gravity, or from any other solid or liquid body, is the figure in which the surface area is the smallest possible that can enclose the given bulk of matter.

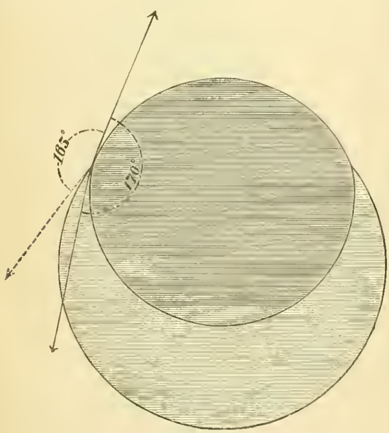

Fig. 3.

I have calculated the period of vibration of a sphere of water[1] (a dew-drop!) and find it to be $\frac{1}{4}a^{\frac{3}{2}}$, where a is the radius measured in centimetres; thus—

For a radius of	$\frac{1}{4}$	cm. the period is	$\frac{1}{32}$	second
,,	1	,,	,,	$\frac{1}{4}$	,,
,,	2·54	,,	,,	1	,,
,,	4	,,	,,	2	,,
,,	16	,,	,,	16	,,
,,	36	,,	,,	36	,,
,,	1407	,,	,,	13,200	,,

The dynamics of the subject, so far as a single liquid is concerned, is absolutely comprised in the mathematics without symbols which I have put before you. Twenty pages covered with sextuple integrals could tell us no more.

Hitherto we have only considered mutual attraction between the parts of two portions of one and the same liquid—water for instance. Consider, now, two different kinds of liquid: for instance, water and carbon disulphide (which, for brevity, I shall call sulphide). Deal with them exactly as we dealt with the two pieces of water. I need not go through the whole process again; the result is obvious. Thirty times the excess of the sum of the surface-tensions of the two liquids separately, above the tension of the interface between them, is equal to the work done in letting the two bodies come together directly over the

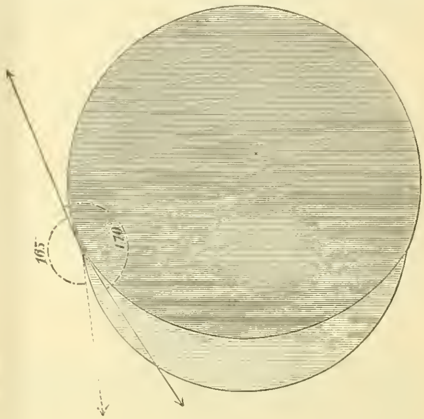

Fig. 4.

supposed area of thirty square centimetres. *Hence the interfacial tension per unit area of the interface is equal to the excess of the sum of the surface-tensions of the two liquids separately, above the work done in letting the two bodies come together directly so as to meet in a unit area of each.* In the particular case of two similar bodies

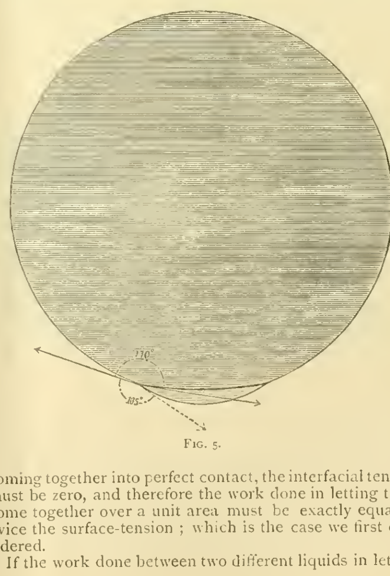

Fig. 5.

coming together into perfect contact, the interfacial tension must be zero, and therefore the work done in letting them come together over a unit area must be exactly equal to twice the surface-tension; which is the case we first considered.

If the work done between two different liquids in letting

[1] See paper by Lord Rayleigh in *Proc. Roy. Soc.*, No. 196, May 5, 1879.

them come together over a small area, exceeds the sum of the surface-tensions, the interfacial tension is negative. The result is an instantaneous puckering of the interface, as the commencement of diffusion and the well-known process of continued inter-diffusion follows.

Consider next the mutual attraction between a solid and a liquid. Choose any particular area of the solid, and let a portion of the surface of the liquid be preliminarily shaped to fit it. Let now the liquid, kept for

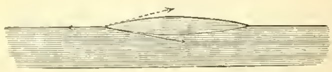

FIG. 6.

the moment rigid, be allowed to come into contact over this area with the solid. The amount by which the work done per unit area of contact falls short of the surface-tension of the liquid is equal to the interfacial tension of the liquid. If the work done per unit area is exactly equal to the free-surface tension of the liquid, the interfacial tension is zero. In this case the surface of the liquid when in equilibrium at the place of meeting of liquid and solid is at right angles to the surface of the

FIG. 7.

solid. The angle between the free surfaces of liquid and solid is acute or obtuse according as the interfacial tension is positive or negative; its cosine being equal to the interfacial tension divided by the free-surface tension. The greatest possible value the interfacial tension can have is clearly the free-surface tension, and it reaches this limiting value only in the, not purely static, case of a liquid resting on a solid of high thermal conductivity, kept at a temperature greatly above the boiling-point of

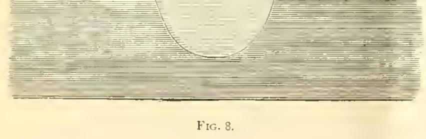

FIG. 8.

the liquid; as in the well-known phenomena to which attention has been called by Leidenfrost and Boutigny. There is no such limit to the absolute value of the interfacial tension when negative, but its absolute value must be less than that of the free surface tension to admit of equilibrium at a line of separation between liquid and solid. If minus the interfacial tension is exactly equal to the free-surface tension, the angle between the free surfaces at the line of separation is exactly 180°. If minus the interfacial tension exceeds the free-surface tension, the liquid runs all over the solid, as, for instance, water over a glass plate which has been very perfectly cleansed. If for a moment we leave the centre of the earth, and suppose ourselves anywhere else in or on the earth, we find the liquid running up, against gravity, in a thin film over the upper part of the containing vessel, and leaving the interface at an angle of 180° between the free surface of the liquid, and the surface of the film adhering to the solid above the bounding line of the free liquid surface. This is the case of water contained in a glass vessel, or in contact with a piece of glass of any shape, provided the surface of the glass be very perfectly cleansed.

When two liquids which do not mingle, that is to say, two liquids of which the interfacial tension is positive, are placed in contact and left to themselves undisturbed by gravity (in our favourite laboratory in the centre of the earth suppose), after performing vibrations subsiding in virtue of viscosity, the compound mass will come to rest, in a configuration consisting of two in-

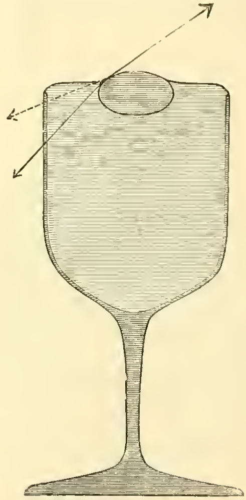

FIG. 9.

tersecting segments of spherical surfaces constituting the outer boundary of the two portions of liquid, and a third segment of spherical surface through their intersection constituting the interface between the two liquids. These three spherical surfaces meet at the same angles as three balancing forces in a plane whose magnitudes are respectively the surface tensions of the outer surfaces of the two liquids and the tension of their interface. Figs. 2 to 5 illustrate these configurations in the case of bisulphide of carbon and water for several different proportions of the volumes of the two liquids. (In the figures the dark shading represents water in each case.) When the volume of each liquid is given, and the angles of meeting of the three surfaces are known, the problem of describing the three spherical surfaces is clearly determinate. It is an interesting enough geometrical problem.

If we now for a moment leave our gravitationless laboratory, and, returning to the Theatre of the Royal Institution, bring our two masses of liquid into contact, as I now do in this glass bottle, we have the one liquid floating upon the other, and the form assumed by the floating liquid may be learned, for several different cases, from the phenomena exhibited in these bottles

and glass beakers, and shown on an enlarged scale in these two diagrams (Figs. 6 to 8); which represent bisulphide of carbon floating on the surface of sulphate of zinc, and in this case (Fig. 8) the bisulphide of carbon drop is of nearly the maximum size capable of floating. Here is the bottle whose contents are represented in Fig. 8, and we shall find that a very slight vertical disturbance serves to submerge the mass of bisulphide of carbon. There now it has sunk, and we shall find when its vibrations have ceased that the bisulphide of carbon has taken the form of a large sphere supported within the sulphate of zinc. Now, remembering that we are again at the centre of the earth, and that gravity does not hinder us, suppose the glass matter of the bottle

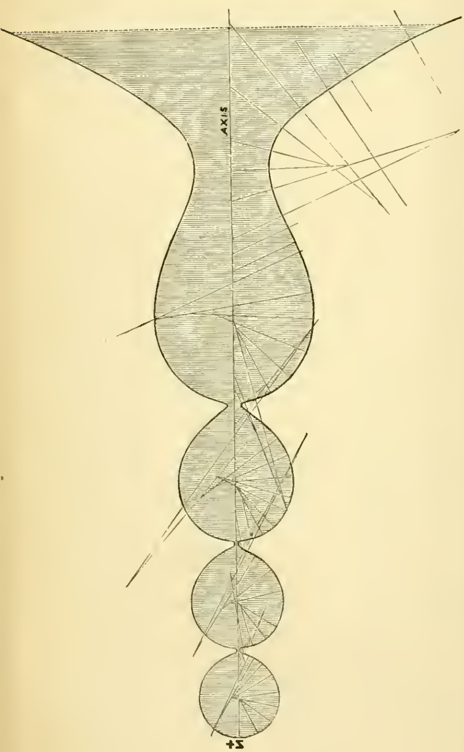

FIG. 10.

suddenly to become liquid sulphate of zinc, this mass would become a compound sphere like the one shown on this diagram (Fig. 3), and would have a radius of about 8 centimetres. If it were sulphate of zinc alone, and of this magnitude, its period of vibration would be about $5\frac{1}{2}$ seconds.

Fig. 9 shows a drop of sulphate of zinc floating on a wine-glassful of bisulphide of carbon.

In observing the phenomena of two liquids in contact, I have found it very convenient to use sulphate of zinc (which I find, by experiment, has the same free-surface tension as water) and bisulphide of carbon; as these liquids do not mix when brought together, and, for a short time at least, there is no chemical interaction between them. Also, sulphate of zinc may be made to have a density less than, or equal to, or greater than, that of the bisulphide, and the bisulphide may be coloured to a more or less deep purple tint by iodine, and this enables us easily to observe drops of any one of these liquids on the other. In the three bottles now before you the clear liquid is sulphate of zinc—in one bottle it has a density less than, in another equal to, and in the third greater than, the density of the sulphide—and you see how, by means of the coloured sulphide, all the phenomena of drops resting upon or floating within a liquid into which they do not diffuse may be observed, and, under suitable arrangements, quantitatively estimated.

When a liquid under the influence of gravity is supported by a solid, it takes a configuration in which the difference of curvature of the free surface at different levels is equal to the difference of levels divided by the surface tension reckoned in terms of weight of unit bulk of the liquid as unity; and the free surface of the liquid leaves the free surface of the solid at the angle whose

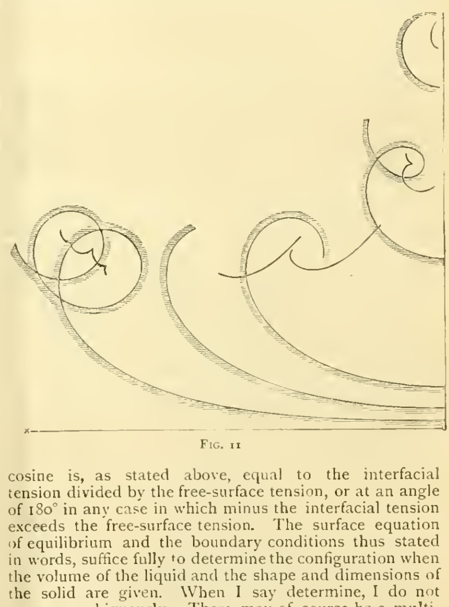

FIG. 11

cosine is, as stated above, equal to the interfacial tension divided by the free-surface tension, or at an angle of 180° in any case in which minus the interfacial tension exceeds the free-surface tension. The surface equation of equilibrium and the boundary conditions thus stated in words, suffice fully to determine the configuration when the volume of the liquid and the shape and dimensions of the solid are given. When I say determine, I do not mean unambiguously. There may of course be a multiplicity of solutions of the problem; as, for instance, when the solid presents several hollows in which, or projections hanging from which, portions of the liquid, or in or hanging from any one of which the whole liquid, may rest.

When the solid is symmetrical round a vertical axis, the figure assumed by the liquid is that of a figure of revolution, and its form is determined by the equation given above in words. A general solution of this problem by the methods of the differential and integral calculus transcends the powers of mathematical analysis, but the following simple graphical method of working out what constitutes mathematically a complete solution, occurred to me a great many years ago.

Draw a line to represent the axis of the surface of revo-

lution. This line is vertical in the realisation now to be given, and it or any line parallel to it will be called vertical in the drawing, and any line perpendicular to it will be called horizontal. The distance between any two horizontal lines in the drawing will be called *difference of levels*.

Through any point, N, of the axis draw a line, N P, cutting it at any angle. With any point, O, as centre on the line N P, describe a very small circular arc through P P′, and let N′ be the point in which the line of O P′ cuts the axis. Measure N P, N′ P′, and the difference of levels between P and P′. Denoting this last by δ, and taking a as a linear parameter, calculate the value of

$$\left(\frac{\delta}{a^2} + \frac{1}{\mathrm{OP}} + \frac{1}{\mathrm{NP}} - \frac{1}{\mathrm{N'P'}}\right)^{-1}.$$

Take this length on the compasses, and putting the pencil point at P′, place the other point at O′ on the line P′ N′, and with O′ as centre, describe a small arc, P′ P″. Continue the process according to the same rule, and the successive very small arcs so drawn will constitute a curved line, which is the generating line of the surface of revolution inclosing the liquid, according to the conditions of the special case treated.

This method of solving the capillary equation for surfaces of revolution remained unused for fifteen or twenty years, until in 1874 I placed it in the hands of Mr. John Perry (now Professor of Mechanics at the City and Guilds Institute), who was then attending the Natural Philosophy Laboratory of Glasgow University. He worked out the problem with great perseverance and ability, and the result of his labours was a series of skilfully executed drawings representing a large variety of cases of the capillary surfaces of revolution. These drawings, which are most instructive and valuable, I have not yet been able to prepare for publication, but the most characteristic of them have been reproduced on an enlarged scale, and are now on the screen before you.[1] Three of the diagrams, those to which I am now pointing (Figs. 10, 11, and 12), illustrate strictly theoretical solutions—that is to say, the curves there shown do not represent real capillary surfaces—but these mathematical extensions of the problem, while most interesting and instructive, are such as cannot be adequately treated in the time now at my disposal.

WILLIAM THOMSON

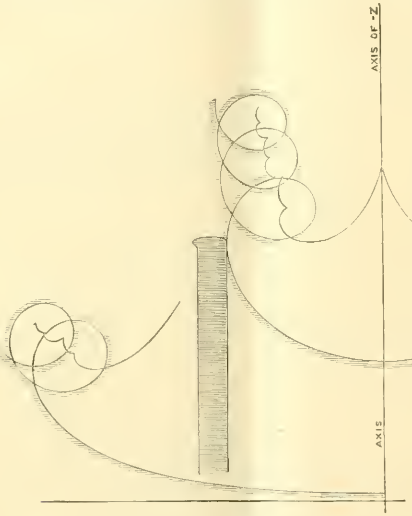

FIG. 12.

THE SCIENCE AND ART DEPARTMENT EXAMINATION IN CHEMISTRY

THE new editor of the "Science and Art Directory" announces a new departure of the most important kind in the teaching of chemistry. In addition to the oral instruction in the elementary stage, there is now introduced an alternative first stage or elementary course intended for those students who only require the elements of chemistry as a foundation for their studies in other subjects.

We give the new syllabus so that it may speak for itself, and congratulate the Department on a step in harmony with the views of the best friends of scientific education in this country.

SOLUTION.—Disappearance of a solid in a liquid by solution. Saturation of a liquid. Effect of increase of temperature on saturation. Effect of lowering the temperature on saturation. Crystallisation. Filtration. Solvent properties of water. Rain, spring, river, and pond waters, &c. Solid matter in different waters; how estimated. Loch Katrine water. Thames water. Sea water. Hard and soft waters. Mineral waters. Similar solvent of other liquids. Solution of one liquid in another. Liquids insoluble in one another. Solution of gases in water and other liquids. The effect of heat on the quantity of gas dissolved by a liquid.

Experiments.—Suspend a piece of white sugar by a thread in a glass vessel containing water. Dissolve salt in water. Show on a balance that sugar or salt and water when separate and when dissolved weigh the same. Show that salt is obtained

[1] The diagrams here referred to are now published in Figs. 10 to 24 of the present report of the lecture at the Royal Institution. These figures are accurate copies of Mr. Perry's original drawings, and I desire to acknowledge the great care and attention which Mr. Cooper, engraver to NATURE, has given to the work.

from the solution by evaporation. Saturate water with nitre, and show that the solubility is increased by increase of temperature. Demonstrate the formation of crystals. Illustrate the removal of substances in suspension, and the non-removal of substances in solution by filtration. Show by evaporation the solid matter dissolved in a sample of pump, or river, or spring water, and explain the method for its quantitative determination. Show the like solvent action with other liquids, as calcium chloride, in alcohol and sulphur in carbon disulphide. Compare the result of admixture of spirit or oil of vitriol with water with that of oil or mercury with water. Heat ordinary water and collect the expelled air.

AIR.—Surrounds the globe. Wind is air in motion Breathing. Air occupies space. The bulk of any quantity of air is much changed by temperature and by pressure. Air has weight. The necessity of air for animals and plants. Bodies when burning require air. Air a mixture of two gases. Oxygen and nitrogen. The proportion of nitrogen to oxygen. Oxygen the active body in air. Bodies burn in it alone and more brilliantly than in air. The combination of oxygen with iron and with other bodies. Increase of weight of bodies which unite with oxygen. Nitrogen does not combine directly with bodies. The nearly constant composition of pure air. Presence of other gases in small amount in air. Water in the air as a gas. The drying up of water.

Experiments.—That air occupies space may be shown by plunging a bell jar into a vessel of water. Fit a flask containing water with an india-rubber plug and delivery tube, heat the water, and collect the expelled air over water. Close the short limb of a syphon tube containing air, and compress the air in the long limb by pouring in mercury. Weigh a flask, fitted with a stop-cock, full of air, and then exhaust by an air-pump, and weigh again. Show that a lighted candle is soon extinguished when burnt under a bell jar, but that it continues to burn if fresh air be from time to time supplied. Burn phosphorus in a tall bell jar over water, and show the diminution of bulk of air. Ignite phosphorus, place it in the remaining gas. Burn some phosphorus under a dry bell jar to show the compound of phosphorus and oxygen which is formed. Place phosphorus in a graduated tube over water to show that at ordinary temperatures it combines with the oxygen of the air and removes it, so that by measuring the volume of gas left, the amount of oxygen contained in air can be roughly determined (to introduce the phosphorus, fuse it in a test-tube under water, and introduce the end of a long wire into it, then let it cool). Burn charcoal and sulphur in oxygen, and call attention to their disappearance. Demonstrate by lime water and by litmus paper that a new body is in each case formed. Burn iron powder (*Ferrum vidactum*) on a scale pan of a balance, to show that an increase of weight occurs. A glass or metal vessel filled with ice or cold water can be used to show the condensation of mixture upon it. Place calcium chloride on the pan of a balance to show the gradual increase of weight which occurs.

WATER.—Its three states. Expansion of water by heat. Equal volumes at different temperatures have not the same weight. Formation of currents in water by heating. Boiling point. Increase of volume on conversion of water into steam. Distillation. Pure water. Hydrogen and its properties. The burning of hydrogen in air, and the weight of the product compared with the weight of the hydrogen; the difference due to oxygen of the air with which hydrogen has combined. Hence oxygen and hydrogen are the constituents of water. Combination of oxygen and hydrogen with explosion to form water. If by measure there be twice as much hydrogen as oxygen, or by weight eight times as much oxygen as hydrogen, then no gas remains—all becomes water. All water composed of these two bodies in this proportion. These two bodies can then be separated from water and can be made to make, unite, and form water. In all cases of chemical combination bodies are united in constant proportion.

Experiments.—Illustrate the characteristic properties of ice, water, and steam. Show that equal volumes of hot and cold water do not counterbalance one another. Fill a flask to the bottom of the neck with cold water, and then heat to show expansion of the water. Show current by heating a large flask of water. To illustrate distillation, distil water containing copper sulphate. Show Liebig's or other forms of condensers. Show the mode of determining the boiling point of a liquid. Show that the temperature remains constant, and that on dissolving substances in water the boiling point is raised. To show the presence of hydrogen in water, pass steam through a red-hot iron tube filled with coarse iron turnings or nails. Water formed of two components, both gaseous. Note the change in the iron both in appearance and weight. This increase of weight and the weight of gas which comes off equals weight of steam which has disappeared. Hence two substances in water, one the combustible gas that comes through the tube, the other the body which remains with the iron. Collect the hydrogen over cold water in proof that it is not steam, also show that it burns. After the tube is cooled show the iron from inside of the tube and explode the oxygen and hydrogen. Plunge a burning taper into jar of hydrogen held mouth downwards, to show burning of the gas and extinction of the taper. Show by a balloon, or soap bubbles, or inverted beaker glass suspended from a balance, that hydrogen is lighter than air. Condense the water formed by the burning of a jet of hydrogen.

Carbon.—Charcoal, graphite, or blacklead and diamond. When wood, sugar, meat, bread are heated carbon remains. Charcoal not changed in the air at ordinary temperatures. Combination of carbon with the oxygen of the air at a red heat. Carbon dioxide a compound of carbon and oxygen. Chemical combination of carbon and oxygen is attended by the evolution of a definite amount of heat expressed by amount of water it will heat. Combustion. The properties of carbon dioxide. Water dissolves carbon dioxide at ordinary temperatures. Action of carbon dioxide on lime-water; no animal can live in this gas. 100 parts of carbon dioxide are composed of 27·27 parts of carbon, and 72·73 parts of oxygen. Carbon dioxide obtained from marble, limestone, oyster-shells, chalk, &c. Charcoal fire. Coal composed of carbon, hydrogen, and a little oxygen, &c.; its burning is the carbon and the hydrogen combining with oxygen. Whenever oil, tallow, coal gas are burnt this carbon dioxide and oxide of hydrogen (water) are formed. Respiration produces similar changes. In expired air the same products arise as from the burning of the food, and there is the same evolution of heat. Carbon a constituent of all animal and vegetable bodies.

Experiments.—Specimens of charcoal. Make charcoal by heating wood in covered crucible. The black lead of a pencil as a specimen of graphite. Sugar heated on piece of tin plate. Show that acids and alkalies do not change charcoal, but that when heated it soon burns away, and only ash is left. Take a small piece of charcoal in a glass tube, pass air over it into lime water, and show no change takes place until the charcoal is made red hot; as the charcoal disappears the lime water becomes milky. Show by means of the balance, or by soap bubbles, or by passing it from one vessel to another, that carbon dioxide is heavier than air, that it acts on lime water, that a burning candle is extinguished in it. Its solubility in water shown by agitating a tube of the gas over water. Prepare the gas from marble by the action on it of dilute acid. Collect all the gas given off from a small piece of marble weighing 5 or 10 grains. Show by collecting in inverted beaker the products of combustion of a candle, of a lamp, and of a gas flame, and adding lime water, that carbon dioxide is given off. Show also by means of lime water that respired air contains this gas.

SULPHUR.—Known also as brimstone. Where found. Its properties. Is also found chemically combined with many metals, so not recognisable by the eye. Sulphur heated in the air melts; more strongly heated it burns, then the sulphur disappears; the strong smell produced belongs to a new body formed by the burning, a compound of sulphur and oxygen. Gaseous properties of the new body, its effect on blue litmus paper, which oxygen and sulphur have not. Its composition is 50·00 parts of sulphur and 50·00 parts of oxygen, and it is called sulphur dioxide. Water dissolves nearly fifty times its volume of this gas, and then turns blue litmus strongly red and has an acid taste. The combination of the gas and water to form sulphurous acid. Another compound of sulphur and oxygen can be made, in which the same weight of sulphur is combined with more oxygen. One hundred parts contain 40 of sulphur and 60 of oxygen, and it is called sulphur trioxide. Sulphur trioxide has properties differing from the dioxide. If the dioxide and oxygen be mixed they do not combine, but if they are passed over hot platinum dense white fumes are formed, which are the trioxide. Combination of the trioxide with water to form sulphuric acid (oil of vitriol).

Experiments.—Show roll and flowers of sulphur and specimen of native sulphur, also iron pyrites and other native sulphides. Powder iron pyrites and heat it in a tube held horizontally over a lamp to show the sulphur obtained from the pyrites. Show the

melting of sulphur by heating flowers of sulphur in small flask. Heat sulphur on a piece of tin plate till it catches fire, show the colour of the flame and observe the smell of burning sulphur. Prepare sulphur dioxide by heating copper turnings in sulphuric acid, and show that it extinguishes flame, is very soluble in water, and that the water dissolving it becomes very acid, turning blue litmus red. Bubble air through a strong solution of sulphur dioxide, and then over platinised asbestos; demonstrate that when the platinised asbestos is hot dense white fumes are formed of the sulphur trioxide. Pour some sulphuric acid into 20 or 30 times its volume of water and prove its acid taste, its action on litmus, and its power of causing effervescence if dropped on sodium carbonate. Show that sulphuric acid is a colourless liquid, that bulk for bulk it is much heavier, more than $1\frac{3}{4}$ times, than water. Show by a thermometer or by immersing a test tube with spirit in it that a large amount of heat is evolved when this acid is poured into water. Pour so ne on sugar or shake it up with oil to show its action on organic bodies.

CHLORINE.—The gas obtained by the action of hydrochloric acid on the black oxide of manganese. So called on account of its colour. Its characteristic smell. Is $2\frac{1}{2}$ times heavier than air and $35\frac{1}{2}$ times heavier than hydrogen. Soluble in water. Many substances take fire in chlorine gas, *e.g.*, phosphorus, and form chlorides. Ignition of oil of turpentine in chlorine with separation of carbon and formation of hydrochloric acid. Bleaching power of chlorine. Bleaching-powder.

Experiments.—Samples of common salt, rock-salt. Prepare chlorine from (1) mixture of common salt, black oxide of manganese and sulphuric acid; (2) from mixture of black oxide of manganese and hydrochloric acid. Collect gas by downward displacement. Draw attention to its colour, and show that phosphorus spontaneously inflames in the gas to form chemical compound of phosphorus and chlorine. Show that oil of turpentine ignites spontaneously in chlorine. Show that sodium when strongly heated burns in chlorine and forms common salt. Show bleaching action of chlorine by dipping moistened Turkey red rag in bottle filled with gas. Show similar action with solution of bleaching powder and acid. Show that chlorine is soluble in water and that the solution has characteristic smell and colour of the gas.

ACIDS.—Are bodies which have sour taste, turn blue litmus red, and liberate carbon dioxide when added to solution of sodium carbonate. Sulphuric acid has these properties. Its specific gravity. Colourless when pure. Evolves heat on being mixed with water. There are two other common bodies which have strong acid properties like sulphuric acid, these are nitric acid and hydrochloric or muriatic acid; these are made of different constituents from sulphuric acid. All act on litmus, &c. in same way; all can be neutralised by potash forming potassium sulphate, or nitrate, or chloride. The compound formed by the union of an acid and alkali is called a salt. All three acids are colourless liquids, but, beside the properties possessed by all acids, each acid has properties which belong to it alone. Nitric acid attacks most metals. Poured on copper the metal is dissolved and red fumes are formed. Hydrochloric acid does not dissolve copper, is not so heavy as sulphuric acid; when mixed with manganese dioxide gives off a yellow irrespirable gas known as chlorine.

Experiments.—Samples of both nitric and hydrochloric acid. Show that they have all the properties belonging to acids and that by neutralising them common salt and nitre can be made. Show the action of nitric acid on copper, tin foil, &c. Show that it has no action on platinum or on gold. Copper placed in hydrochloric acid not attacked, but if mixed with manganese dioxide and warmed chlorine is given off.

ALKALIES.—Are another class of bodies which turn red litmus blue; have soapy taste and absorb carbon dioxide. If potash be added gradually to sulphuric acid the properties of both bodies gradually disappear, and at last a liquid is obtained that has no action on litmus. The combination of acid and alkali and the body formation of sulphate of potash or potassium sulphate; sulphate of soda or sulphate of ammonia can be formed in a similar manner.

Experiments.—Show that solutions of potash, soda, and ammonia turn reddened litmus blue, and that when a tube containing carbon dioxide is inverted in any of these solutions the gas is absorbed. The taste of these bodies is soapy not sour. Add gradually to dilute sulphuric acid one of these bodies, and see that the acid character of the dilute sulphuric acid disappears. Neutralise exactly sulphuric acid with potash, then evaporate and crystallise out the salt formed.

AMMONIA.—A gas with a very pungent smell. Solution in water. One volume of water dissolves 800 volumes of ammonia. This liquid has the pungent smell of the gas, and it can neutralise the strongest acids. Formation of ammonium chloride or sal ammoniac by ammonia with hydrochloric acid. Ammonium chloride a white solid, soluble in water, with no smell of ammonia. Ammonium chloride a volatile body. The effect of boiling a solution of ammonium chloride with lime or potash. Ammonia is composed of 82·3 parts of nitrogen and 17·7 parts of hydrogen. The pungent odour of smelling salts is due to ammonia. Animal matters, such as horn, dried flesh, glue, cheese, isinglass, heated so as to decompose these bodies, yield ammonia. The formation of ammonia in large quantities by heating coal to make coal gas. Production of ammonia when animal matters containing nitrogen putrify.

Experiments.—Prepare ammonia by treating ammonium chloride with an equal weight of slaked lime and enough water to make the whole into a thick mud; and demonstrate its smell, its action on red litmus, and its great solubility in water. The gas passed into water, the increase of volume of the liquid. Its properties and their identity with those of the gas. Volatility of ammonia shown by the liquid leaving no residue on evaporation. Show that ammonium chloride is formed by neutralising a solution of ammonia with hydrochloric acid, and is obtained as a solid on evaporation, and that on further heating it is volatilised. Heat coal in a coarse powder in a glass tube, and show that the liquid obtained is very alkaline. Show the formation of ammonia by the addition of potash and lime to a solution of ammonium chloride.

LIME AND CLAY.—Limestone, marble, oyster-shells, chalk, all contain a metal known as calcium. The oxide of this metal known as lime. Lime and carbon dioxide are together present in limestone, marble, shells, and chalk. When these are strongly heated, especially in a current of air, the carbon dioxide is evolved and the lime is left. Action of water on lime. Its use in making mortar. Lime slightly soluble in water. On blowing carbon dioxide into a clear solution of lime (lime-water), liquid becomes turbid, owing to combination of carbon dioxide and lime to form chalk. Same effect on breathing through lime-water. Other important salts of lime are gypsum or plaster of Paris (sulphate of lime) and phosphate of lime, which exists largely in bone. Clay is a combination of a body called silica, which is the chief constituent of sand and flint, with the oxide of a metal known as aluminium, so called because it exists also in alum. Glass is a compound of silica with lime and an alkali, potash or soda. Varieties of clay; their use in manufacture of bricks and pots. The metal of clay (aluminium), a white body with a brilliant lustre, $2\frac{1}{2}$ times heavier than water; may be rolled out into thin sheets and drawn into fine wire. Not oxidised in the air.

Experiments.—Samples of limestone, marble, oyster shells. Show that these substances effervesce with dilute hydrochloric acid, and that a gas carbon dioxide is evolved. Heat a piece of limestone or marble to redness in a fire, and show that after heating it no longer gives off carbon dioxide on treatment with an acid. Describe process of lime-burning. Properties of lime as distinguished from limestone. Show that a piece of moistened red litmus paper pressed against limestone is not affected, but that when pressed against lime it is turned blue. Show slaking of lime; draw attention to heat evolved. No such result on treating limestone with water. Show that lime is soluble in water, whereas limestone is not. Add carbon dioxide to the solution of lime, and show that white powder is formed which on treatment with acid evolves carbon dioxide again. Explain that white powder thus formed is identical in chemical composition with limestone, and hence that limestone is a compound of carbon dioxide and lime. Explain use of lime in making mortar. Various samples of clay are used in manufacture of bricks and pots. Show plasticity of clay and exhibit one or two specimens of ware before being baked. Show that a vessel of kneaded or "puddled" clay will hold water. Explain chemical nature of clay, and show specimens of silica and alumina. Show alum and demonstrate that alumina is contained in it by heating ammonia alum. Show specimen of aluminium and explain that this metal is contained in alumina and therefore in clay.

METALS, INTRODUCTORY.—About 70 different elementary subjects known. Almost all the common metals are elements. For instance, iron, lead, copper, zinc, mercury, silver, gold, tin, are elements. All combine with oxygen to form oxides, with chlorine to form chlorides, and with sulphur to form sulphides.

Experiment.—Specimens of metallic and non-metallic elements and of oxides and sulphides.

LEAD.—Its colour; a fresh surface bright, but soon tarnishes in the air. Is heavy. Lead is $11\frac{1}{2}$ times heavier than water. Can be beaten or rolled into thin sheet or drawn into wire. Melts at temperature 633° F. Can be cast in a mould. Its combination when liquid with oxygen. Formation of lead oxide. The oxide has entirely different properties from lead. Removal of the oxygen when heated with carbon and the formation of metallic lead. Formation of red lead by heating the oxide. Solution of lead by nitric acid and the formation of lead nitrate. Solution of lead oxide by nitric acid and the formation of lead nitrate. Similarly to potassium nitrate this is to be termed "a salt." Its solution in water. Other salts of lead, chloride, sulphate. Formation of sulphate and chloride of lead, their insolubility in water. Galena, or lead sulphide, one of the ores from which lead is obtained.

Experiments.—Piece of lead to scrape and show it is then bright and has "metallic" appearance. Show by balance that compared with water it is bulk for bulk much heavier. Show the metal beaten out into thin sheet, also as wire. Melt lead in an iron spoon, and cast in a mould. Show formation of oxide by blowing air on to the melted metal. Contrast the properties of the oxide with those of the metal. Convert the oxide again into metal by strongly heating an intimate mixture of it and charcoal powder. Heat the oxide to show its further oxidation and the formation of red lead. Show the action of nitric acid on lead, also on lead oxide, and the formation of lead nitrate. Show this is "salt," and prove that it is soluble in water. Demonstrate that the first is very slightly soluble, and the last almost insoluble in water. Show the formation of chloride and sulphate of lead by the addition of the respective acids to a solution of lead nitrate. Collect on filter the salts so formed, wash and dry them. Show specimen of Galena (lead sulphide).

IRON.—Not used in a pure condition, always obtained united with carbon. Three kinds of iron; wrought iron, cast iron, and steel. Wrought iron the purest and used if the body is to be formed by hammering. Cast iron contains most carbon. Steel used for cutting instruments; can be made into a magnet; can be "annealed." Solubility of all three forms of iron in sulphuric, nitric, and in hydrochloric acids, and the formation of iron sulphate, nitrate, and chloride. Their solubility in water. Melting point of iron is at much higher temperature than that of lead. Comparison of the weight of iron with that of water. Its colour. The ready action of air on it. Formation of rust. Oxidation by heating. The action of steam on iron when red hot. Oxide of iron heated with hydrogen or with carbon parts with its oxygen, and iron is left. Oxide of iron found in the earth. Hæmatite. A carbonate of iron mixed with clay used as a source of iron. Heating the ore the iron is converted into oxide. Removal of the oxygen by heating it to a very high temperature with carbon. Formation of slag from clay and lime.

Experiments.—Specimens of the different kinds of iron, wrought iron, cast iron, and steel. Dissolve cast iron in hydrochloric acid diluted with equal volume of water, show carbon which remains, filter and evaporate the liquid to show the chloride of iron formed. Heat iron wire by the blowpipe to show the high temperature required to fuse it. Iron acted on by air and moisture to show its rusting. Heat iron oxide in a tube and pass hydrogen over it to show formation of water and metallic iron. Show specimens of iron ores, clay iron stone. Hæmatite magnetic iron ore, and slag.

COPPER.—Its colour. Does not rust in air at ordinary temperatures. Thin wire melts in flame of Bunsen burner. When heated in air becomes black, owing to formation of an oxide. Oxide heated in hydrogen gas yields up its oxygen, water is formed, and the red-coloured copper is obtained. Action of acids on copper. With dilute nitric acid evolves a colourless gas, which turns red in contact with the air, and the metal dissolves, forming a green solution of copper nitrate. Heated with sulphuric acid copper yields sulphur dioxide, the same gas which is formed when sulphur burns in air or in oxygen. Substance formed when copper dissolved in sulphuric acid is when crystallised from water of a fine blue colour, known as copper sulphate or blue vitriol. Action of vegetable acids on copper. Verdigris. Use of copper In alloys. A penny composed of 95 parts of copper, 4 parts of tin, and 1 part of zinc. Bell metal and gun metal contain copper and tin.

Experiments.—Show specimens of copper in bar, sheet, and wire. Point out characteristic colour of metal. Heat piece of sheet copper over flame of Bunsen burner. Show formation of black film. Explain its origin. Take black oxide of copper and heat in hydrogen gas. Show that metal is again formed and that water is produced. Show action of nitric and sulphuric acids upon copper. Exhibit specimen of copper sulphate (blue vitriol). Show that on placing a knife blade in a solution of copper sulphate metallic copper is formed on the steel. Show sample of verdigris and explain how formed. Show various alloys of copper, bell-metal; brass, gun-metal, &c., a penny-piece.

MERCURY.—A liquid metal, but if it be cooled to − 40° Fahrenheit it is solid. Its metallic appearance. Its weight; heaviest liquid known; 13·6 times heavier than water. Use in the barometer and thermometer. Does not rust or tarnish in the air at ordinary temperatures, oxidation if heated to about 600° F. in the air, and the formation of red mercuric oxide. Is readily attacked and dissolved by nitric acid. It dissolves many metals, —*e.g.*, tin, lead, &c.; amalgams. Mercury in combination with sulphur, as cinnabar. Mercury can be obtained from any salt of mercury by heat, volatilization of mercury, and the condensation of the vapour.

Experiments.—Specimen of mercury. Show that to balance a given volume of mercury $13\frac{1}{2}$ volumes of water are necessary. Boil a little mercury in a tube to show it vaporizes. Treat mercury with nitric acid and show its solution. Show that tin foil is dissolved by mercury, which becomes less fluid. Heat mercuric oxide in a tube and collect both the oxygen and the mercury. Heat mercuric chloride in tube sealed at one end with dry sodium carbonate and show the metallic mercury condensed on the side of the tube.

SODIUM.—Common salt contains a metal combined with chlorine known as sodium. 100 parts of common salt contain 39·3 parts of Sodium and 60·7 parts of Chlorine. Carbonate of soda (washing soda) contains sodium. Sodium obtained on strongly heating carbonate of soda with charcoal. Sodium one of the lightest solids known. Swims on the surface of water and decomposes that liquid with evolution of hydrogen and formation of the alkali soda. Other properties of the metal sodium: its low fusibility and softness. Its tarnishing in air. Preservation of sodium from action of air by being kept in same liquid lighter than water and free from oxygen.

Experiments.—Samples of common salt and rock salt; also washing soda and bicarbonate of soda. Recall experiment showing that chlorine is constituent of common salt. Show that washing soda and sodium bicarbonate evolve carbon dioxide on treatment with an acid. Common salt a compound of chlorine with a metal called sodium; bicarbonate of soda and washing soda compounds of carbon dioxide and sodium. Sodium can be made by strongly heating sodium carbonate with charcoal. Exhibit specimen of portions sodium. Show that it can be cut with a knife, and that the so cut can be pressed together again. Exhibit metallic lustre of sodium; show that it quickly tarnishes in the air. Show that sodium is lighter than water and decomposes that liquid with evolution of gas (hydrogen). Collect hydrogen from water by thrusting small piece of sodium beneath test-tube filled with water and standing in basin of water.

CARBON COMPOUNDS.—Large numbers of substances are met with in plants and animals which are not found in the earth. Most of these bodies contain carbon. The other elements united with the carbon are hydrogen, oxygen, nitrogen; some bodies are composed of all these elements; others of only two of them. Many of these bodies when heated leave black residue of carbon; when this is more strongly heated it burns away. The great number of these carbon compounds, and the great difference in their properties. Some are acids, *e.g.*, vinegar (acetic acid), and tartaric acid. Some are salts, *e.g*, fats, tallow, butter. Some are neutral bodies, *e.g.*, sugar, starch, spirit.

Experiment.—Show that on heating any ordinary vegetable or animal substance carbon is left behind.

ACETIC ACID.—One form of dilute acetic acid is known as vinegar. Formation of acetic acid when beer or wine exposed to the air becomes sour. The spirit present combines with oxygen of the air and forms acetic acid. The presence of a kind of fungus called *mycoderma aceti* necessary to cause this oxidation. Large amount of vinegar is made from poor kinds of wine and beer. Action of vinegar on blue litmus, and on sodium carbonate. Vinegar is also made by heating wood in a retort; a great many bodies distil over, among them acetic acid. The pure acid has very pungent smell, and has all the properties which are characteristic of the acids. Boils at 246° F. Dissolves in water. It is composed of carbon, hydrogen, and oxygen in the proportion of 40·0 parts of carbon, 6·7 parts of hydrogen,

and 53·3 parts of oxygen. It is neutralised by alkalies like sulphuric acid. Iron put into it is slowly dissolved, hydrogen being given off. Oxide of lead dissolves in it, forming a salt, and if the clear solution be evaporated a white crystalline body called "sugar of lead" is formed, which is lead acetate. The vinegar smell belongs only to the acid, not to the salts. Sodium acetate has no smell; add to it sulphuric acid and warm, when the smell shows the acid has been liberated and that it is volatile.

Experiments.—Show that vinegar has the properties of an acid, and that a salt is formed on neutralising it. Show a specimen of the commercial acetic acid, and point out its colourless appearance and strong smell and acid reaction. Show that iron is acted on and dissolved by acetic acid. Make sugar of lead by dissolving lead oxide in acetic acid, and crystallise out the salt. Point out disappearance of the pungent odour of the acid on neutralisation by potash or soda. Demonstrate the liberation of the acid as indicated by the odour on addition of sulphuric acid to sodium acetate, and show that it can be separated from the liquid by distillation.

TARTARIC ACID.—Occurs in many fruits; especially in grapes. Is obtained from "argol," an impure potassium salt of tartaric acid, deposited when grape juice ferments. Tartaric acid is a crystalline solid, and dissolves easily in water. Has no smell. Is composed of carbon, hydrogen, and oxygen, *i.e.*, the same elements as are in acetic acid but in different proportions, viz.: 32·0 parts of carbon, 4·0 parts of hydrogen, and 64·0 parts of oxygen. Its action on sodium carbonate. Effervescing draughts; seidlitz powders. Tartrates.

Experiments.—Specimen of argol and of crystals of tartaric acid. Show solubility of the solid acid in water, and that the solution has acid properties and is without odour. Demonstrate the presence of carbon in the acid by ignition.

FAT AND OILS.—Are neutral bodies made up of an acid and a base, the base in all cases is glycerine, the acid varies in different oils and fats. They are all insoluble in water. Oils are liquid; fats are solid. Many of the oils are obtained from vegetables, either from the seed or fruit. Most of the fats are from animals. Melting of tallow (fat of the ox, sheep, &c.) put in boiling water. Its non-solution in water. Its lightness as compared with water. If a solution of caustic potash be added, and the solution of the liquid boiled, the fat disappears and the liquid becomes slightly milky, and nearly the whole dissolves. Combination of the potash with the acid (stearic) of the tallow and formation of potassium stearate. Previously the stearic acid was combined with glycerine. To the solution of potassium stearate hydrochloric acid is added. The potash is again separated from the stearic acid, and the stearic acid, as it cannot dissolve in water, separates out. Stearic acid dissolves in alcohol and in ether and separates out in crystals. Used in making candles, and is better than tallow because it melts at a higher temperature. Tallow distilled with steam of temperature 600° F. (high pressure steam) separates into stearic acid and glycerine, and when cold these bodies remain separate. All oils and fats are decomposed by potash in the same way as tallow.

Experiments.—Tie beef or mutton fat up in muslin bag, and melt to separate the fat from membranous matter. Show that fat is insoluble in water, that it floats on water, and melts at a temperature below boiling water. Show that oil has very similar properties to melted fat. Boil oil or fat with caustic potash. Prepare a solution of potassium stearate, and precipitate stearic acid from it by the addition of hydrochloric acid. Show the solubility of the acid in alcohol and ether, and the insolubility of the lime salt of stearic acid.

GLYCERINE.—A thick colourless liquid with a sweet taste. Dissolves readily in water. When quite pure becomes solid at a low temperature. If heated alone it is destroyed, but if heated with water in a retort it distils over with the steam. Heated with acids it combines with them, and bodies similar to fats are formed.

Experiment.—Specimen of glycerine. Demonstrate its solubility in water and its sweet taste.

SOAP.—By boiling fat with caustic soda sodium stearate is formed. On adding salt to the liquid the sodium stearate, which is soap, separates out and solidifies on the surface of the liquid. Soft soap is potassium stearate. Action of soap in washing. Action of soap on hard and on soft waters.

Experiment.—Shake distilled water up in bottle with soap. Show action of solution of salts and acids on the solution. Add soap solution to distilled water, also to common water, and explain the difference of action. Show the presence of stearic acid in soap by adding hydrochloric acid to a solution of soap.

SUGAR.—Exists in many plants. Is obtained from the sugar-cane; also from beetroot. The juice of these plants yields the sugar. When pure it is white, crystalline, sweet, and very soluble in water. Sugar candy. If heated with very little water to 365° F., on cooling it is no longer crystalline and is "barley sugar." Does not combine with acids, but even a very little acid boiled for a long time with a solution of sugar changes it to another kind of sugar. Composition of cane sugar. The several different kinds of sugar, *e.g.*, the solid part of honey is a sugar which differs from the sugar in the sugar-cane; the same found in all sweet fruits and is called grape-sugar. Grape-sugar not so sweet nor so soluble as cane-sugar.

Experiment.—Specimens of ordinary white and brown sugar; also sugar candy and barley sugar. Show its great solubility in water; also that its solution is neutral. Heat it and point out the peculiar odour it gives out, and that on further continuing the heat it leaves a residue of carbon. Wash honey with spirit, and show the residue is sugar, but that it is not sweet as ordinary sugar, and not so soluble.

STARCH.—A neutral substance, composed of carbon, hydrogen, and oxygen. Composition. Peculiar structure; not crystalline. Is found in all parts of a plant. Is obtained from wheat, rice, potatoes, arrowroot, &c. Starch in its ordinary condition insoluble in water. When starch powder is boiled with water, the membrane of starch cells bursts, and the starch is partially dissolved. Strong solutions form a jelly when cold. Used for stiffening linen. Starch recognised by its forming a blue compound with iodine. Undergoes no change in the air at ordinary temperatures; if heated to about 300° F. it becomes slightly discoloured and is changed into a soluble body, known as British gum (dextrin). If small amount of nitric or hydrochloric acid be added to the starch this change is more rapid. Extract of malt also changes starch into soluble compounds. Starch as a food.

Experiment.—Specimen (of starch), point out its peculiar structure and absence of crystalline form. Demonstrate that it does not dissolve in cold water, but on boiling some does dissolve. Show that starch both solid and in solution gives a blue colour when iodine is added to it. Moisten starch with very dilute hydrochloric acid, and heat to convert it into a gum, which is thus soluble in water.

GLUTEN.—If flour is tied up in a calico bag and well kneaded in a basin of water, the water becomes milky, and on standing starch sinks to the bottom. All the starch in the flour can thus be removed, and then a sticky substance remains in the bag called gluten. About 70 per cent. of flour is starch and 10 per cent. is gluten. Gluten contains nitrogen, starch does not. These bodies represent two most important constituents of food. The gluten exposed to the air soon decomposes and smells very disagreeably (putrifies).

Experiment.—Tie some flour up in a piece of calico and knead it for some time in a vessel of water; the starch comes through, and will settle to the bottom of the vessel, and can be collected and examined; the gluten remains in the bag.

SPIRIT.—Alcohol, spirits of wine. A colourless, light liquid. Neutral to test papers. Has pleasant odour, boils at 173° F. Burns with a flame, which gives very little light, without leaving any black residue of carbon. A large number of different bodies dissolve in it. It is the intoxicating principle in wines and spirits. In beer there is 3 to 5 per cent. of alcohol. In light wines about 8 per cent. In spirits 60 to 75 per cent. The different flavours of wines and spirits depend on very small quantities of other bodies present. Alcohol dissolves in water, giving out heat.

"Proof spirit" contains 50·76 parts of water, and 49·24 parts of alcohol. If more water be present the spirit will not set fire to gunpowder when burning. Alcohol obtained from grape sugar. Fermentation grape sugar converted into alcohol and carbon dioxide by presence of some ferment which exists in yeast. Cane sugar on the addition of yeast is first converted into grape sugar, then into alcohol and carbon dioxide. Use of yeast in brewing. Not necessary for making wine, as there is already a ferment in expressed juice of grape.

Experiment.—Show it is neutral liquid dissolving in water, that it burns with nearly colourless flame, and leaves no residue of carbon. Show that it can be made to boil at much lower temperature than water by placing test-tube of it in hot water. Distil beer and collect the alcohol and water which comes over;

add quicklime to this. Allow it to stand some hours, and distil again. Show that this is much stronger, catches fire readily, and tastes more burning. Make a solution of common sugar in a large flask; add yeast, and fit a cork with a bent tube to the flask. Let the tube dip into lime water. Place it in a warm place, and after some days show that spirit has been formed in the flask by distilling the liquid and collecting the portion coming over first.

All the substances and experiments mentioned above are to be shown to the class. This does not preclude such other experiments and illustrations as may suggest themselves to the teacher.

NOTES

WE trust that it is not in the least likely that the proposal "From a Correspondent" in Saturday's *Times* to remove the Science Museum to make way for a permanent Colonial Museum will receive serious attention in any influential quarter. For this proposal really involves the monstrous step of shunting collections which have been brought together with so much trouble and at so much expense. Their value was recognised by the Duke of Devonshire's Commission. As to the Colonial Museum we shall be in a better position to express an opinion upon it when its nature and objects are further developed. We wish in no way to disparage it; but there is room for it elsewhere. Why should its founders try to build it on the ruins of an existing and valuable collection?

THE thirty-fifth meeting of the American Association for the Advancement of Science will be held at Buffalo, from Wednesday, August 18, until Tuesday evening, August 24, 1886. For the third time, at intervals of ten years each, the Association has accepted an invitation to hold a meeting in Buffalo. The Local Committee intend to make the meeting a great success: and members who were at the meeting of 1876 need only to recall it in order to form an idea of what the coming meeting promises to be. The facilities which the city offers are all that can be desired, both in regard to rooms for the several Sections and in hotel accommodation, while the health and comfort of the city in the month of August are well known. The headquarters of the Association will be at the High School, and all the offices and meeting-rooms will be in that building or in one of the schoolhouses near by. The hotel headquarters will be at the Genesee House. A special circular in relation to railroads, hotels, and other matters, has been issued by the Local Committee. Arrangements for excursions and receptions will be announced by the Local Committee. The officers of Sections D and H have issued special circulars relating to the meeting, which can be had by addressing the respective secretaries. Special information relating to any of the Sections will be furnished by their officers. In Section E special attention will be given to the problems connected with the Niagara Falls and its gorge.

WE have only just received the *Proceedings* of the American Association for the Advancement of Science at the Philadelphia meeting of 1884. The volume is particularly well printed and fully illustrated.

THE Institution of Naval Architects is holding a summer meeting at Liverpool this week.

THE recent elections have done nothing to alter the comparatively small but distinguished band of men of science in the House of Commons. Sir John Lubbock retains his seat for London University. The electors of South Manchester have remained faithful to Sir Henry Roscoe, and those of South Leeds to Sir Lyon Playfair. Mr. Story-Maskelyne returns from North Wiltshire, and Sir Edward Reed, after one of the principal contests of the election, from Cardiff.

M. JANSSEN is continuing, at Meudon, his researches on the influence of gases on the rays of the spectrum. He is building tubes, which can be loaded with 1000 atmospheres of hydrogen, oxygen, or carbonic acid. In this last case the real density of the gas will be superior to the density of water. The filling of the tubes to these high pressures is not directly obtained by pressure; they are loaded by a sort of step-by-step or cascade process. This is a very long affair. After the filling of these tubes some time must be allowed for the settling down of the dust which has been raised by compression. As long as the cloud of minute particles is floating, the colour of the light traversing longitudinally the tubes is blood-red. This effect can be shown with a far lessened pressure.

MR. J. M. HORSBURGH has been appointed Secretary of University College, London, to enter upon his duties on October 1.

DURING the last ten years M. Marcel Deprez has been engaged in experiments connected with the transmission of force by means of electricity. The Rothschilds some time since provided him with an unlimited credit to prosecute his researches at Creil, under the inspection of a commission of thirty-eight men of science. On Friday the commission met to hear a report on the results at present obtained, drawn up at their request by M. Maurice Lévy. This report was unanimously approved. It appears from it that we can now, with only one generator and only one receiver, transport to a distance of about 35 miles a force capable of being used for industrial purposes of 52-horse power, with a yield of 45 per cent., without exceeding a current of 10 ampères. When the amount of force absorbed by the apparatus used to facilitate the recent experiment, but not required in the applications to industrial purposes, is added, the yield will be nearly 50 per cent. The commission certifies that the machines now work regularly and continuously. The maximum electromotive force is 6290 volts. Before the construction of the Marcel Deprez apparatus the maximum force did not exceed 2000 volts. The report states that this high tension does not give rise to any danger, and that no accident has occurred during the past six months. The commission is of opinion that the transmitting wire may be left uncovered on poles provided it be placed beyond the reach of the hand. It estimates at nearly 5000*l.* the probable cost of the transmission of 50-horse power round a circular line of about 70 miles. This price would, however, be much diminished if the machines were frequently constructed. The commission, in the name of science and industry, warmly congratulated M. Deprez on the admirable results which he had obtained, and expressed thanks to the Rothschilds for the generous aid extended to the undertaking.

THE eighth congress of the French Geographical Societies will meet at Nantes on the 4th proximo, and will continue until the 9th.

IT is stated that Baron de Miklouho-Maclay is now busy getting printed at St. Petersburg, by command of the Czar, the result of his scientific researches in New Guinea from 1870 to 1883.

A CONFERENCE was held by the National Fish Culture Association on Monday last at the Colonial and Indian Exhibition. Sir Albert K. Rollit, M.P., presided. The chairman, in delivering the presidential address, stated that the Association had made a great impression upon the public as to the necessity for remedial, protective, and other measures in the interest of our fishing industries and population. The Association was doing work which many other nations and colonies thought it expedient and economical to do upon a much larger and more expensive scale. He therefore thought the public ought to support it liberally in order to enable it to carry out the work which could

not be left undone without serious danger to one of the greatest industries of this country. Mr. Oldham Chambers then read a paper upon "Carp Culture," which was followed by the Rev. C. J. Steward with a paper upon "Marine Temperatures and their Influence upon Fishes," and Mr. Willis-Bund with a paper upon "The Influence of the Weather upon the Migration of Fish." After the several papers had been fully discussed, the proceedings terminated with a vote of thanks to the chairman for presiding.

IN a recent article the *Ceylon Observer* refers to the power of the coco-nut palm to conduct lightning. Sir Emerson Tennent long ago pointed out that this tree acts as a conductor in protecting houses from lightning, and in one instance 500 palms were struck in a single plantation during a succession of thunderstorms in April 1859. But the trees themselves suffer terribly in the process, for however slightly they may be touched by the electric fluid, they die. Sometimes only the edges of the branches are singed, at others a few leaves turned brown alone show where the tree was touched, yet however slight the apparent effect, in course of time the tree withers gradually and dies. In conclusion the journal quoted inquires why it is that coco-nut palms which have merely had their external parts, their foliage, almost imperceptibly singed should be as much doomed to death as those which have had their vital parts permeated by the lightning, the fatal result being only protracted in the one case, while it is instantaneous in the other.

AT Nottingham the University College, Technical Schools, and a Museum are under the same committee as the Free Library; and from the not very carefully edited Report of that committee the convenience of combination is further shown by special classes being opened at the first of them for elementary school teachers, while the expense is defrayed by the School Board. The Technical Schools, whose evening class students we trust will far exceed in number the regular daily pupils, are largely supported by voluntary contributions from the Drapers' Company; so natural and appropriate a use to put such money to, that it is to be hoped that the reforming spirit of the age will lead to the same commendable action voluntarily on the part of all such old trade guilds. As might easily have been foreseen, commercial classes held during the working hours of all those who felt their need have failed; just like the free library at the Guildhall, London, so discreetly opened at first from ten till four —just the hours when the pressure of business was greatest upon every one to whom it could be of any use! An experience of the Nottingham Committee seems to be that the highest working power of their money may be obtained by opening district branches, modestly termed reading rooms, yet each the germ of a branch library; and also that the most economical size for a free library, as far as supplying literature to the working classes is concerned, is from three to four thousand volumes; their libraries of that size having a greater circulation in proportion than either the larger or the smaller ones.

WE have received the first number of a new technical journal named *Industries*, published in Manchester. As its name implies it is the intention of the publishers that it shall cover all the ground of the manifold manufactures of the country, and include the dissemination of technical education in its widest and most useful form. A new departure is taken in technical journalism, inasmuch as the publishers propose to offer a series of substantial rewards to those of their readers who may bring forward some new and useful advance in practical science. These awards will be granted on certain conditions being fulfilled, and will be made by the editors, assisted by two or more gentlemen eminent in the particular science. As a commencement it is the intention to arrange rewards in each of the following subjects, viz. engineering, electricity, and chemistry. In order to increase the value of the reward, and should the successful reader desire it, a patent will be obtained by the publisher for the invention or process, which will be presented to the successful reader before the invention is described in the paper, and further, if a model is necessary, this also will be added to the reward. This inducement ought to add considerably to the subscribers' list, and ensure the success of the paper; at the same time it will without doubt increase, the number of workers and probably add to the already large list of inventions. The paper is nicely printed, and the woodcuts are well executed. We find an illustrated Patent record at the end of the journal, and arrangements are to be made so as to include the more important American and German Patent Specifications. Journals of this class add greatly to the general advancement of technical education, and we wish the new venture every success in its youth and a strong and sturdy future.

A MOSCOW journal states that it is contemplated establishing a university for women in that city, founded on private capital. It is to have three faculties—a mathematical, a natural history one (with medicinal studies), and a philological. Doubt is, however, expressed whether the Government will sanction the scheme.

FROM several parts of Western Norway complaints are being received of the great destruction of fir and spruce cones by a little unknown insect.

FROM the report of the Swedish Academy of Sciences for last year, it appears that the National Museum—which is under the authority of the Academy—succeeded in acquiring some splendid specimens of topazes from Brazil, containing fluids on which experiments are now in progress in the Academy's chemical laboratory. Some specimens of argyrodite, containing the new element germanium, were also acquired, with which Profs. Nilsson and Petterson have been experimenting. The museum for lower invertebrates acquired from Lieut. Sandberg a very valuable collection of lower marine animals from the shores of Northern Russia, collected by this gentleman during his extensive journeys in these parts. At the Academy's biological station on the coast of the province of Bohus, aquaria were kept in perfect working order from June till October. The station was visited by many *savants* for zoological studies. Through Dr. Carlson's researches on the former existence in Sweden of *Trapa natans*, the National Museum has become possessed of more than a thousand sub-fossil trapa fruits from Southern Sweden. In addition to the sums granted by the Government towards scientific researches on the recommendation of the Academy (p. 201), several others were made out of the funds administrated by that institution. Among them are the interest on the large sum left by the late Dr. Regwell for zoological studies, distributed for the first time; a sum of 250*l.* to Dr. S. Arrhenius for the study of the galvanic conductive force of electrolytes, and their relation to physics, at certain institutions in Russia, Germany, and Holland. Prof. Agardh was awarded the yearly Lettersted prize for his celebrated work "Fresh contributions to the Systematic of the Algæ." The Lettersted fund for scientific research amounted at the end of the year to 30,000*l.* A number of smaller sums were also granted by the Academy towards researches on a variety of scientific subjects.

MR. OTIS T. MASON sends us a reprint of his valuable paper on the progress of anthropology in 1885, which was originally embodied in the Smithsonian report for that year. Here anthropology is used in a very wide sense, giving scope to remarks on comparative psychology, biology, archæology, and sociology, as well as to the more closely-connected subjects of general and special ethnology. Some of the more important recent works

on these several branches are noticed in greater or less detail, and there is appended an ample "Bibliography of Anthropology, 1885," which is arranged in alphabetical order, and which will be found most useful for purposes of general reference. It includes not only independent works and memoirs, but also special papers bearing on the subject, which have been contributed in the specified period to various English, American, French, German, and other scientific journals. Amongst the essays more fully noticed are M. Gabriel de Mortillet's work on "The Precursor of Man," advancing the theory that the flints of Thenay were the workmanship, not of man as fully developed, but of his immediate predecessor, the anthropopithecus; Dr. Lissauer's paper on human craniology, introducing the sagittal suture as a new element in obtaining anthropological measurements; Dr. Hermann Welcker's treatise on the capacity of the cranium in connection with the three diameters, with classifications of races according to their skull capacity; Dr. Topinard's masterly work on general anthropology, from which copious extracts are made; Dr. Otto Stoll's contribution to the comparative philology of Central America, embodying a scientific classification of the eighteen languages still current in Guatemala. Here the Maya family is specially dealt with and divided into four distinct groups: Tzental (Chendal), Pokonchi, Quiché, and Marne. It is incidentally mentioned that in 1885 the Woman's Anthropological Society was organised in Washington under the presidentship of Mrs. Tilly Stevenson. The object of this association is stated to be "to conduct investigations to which the avenues are especially open to women, and to encourage the sex in the prosecution of scientific work."

THE catalogue of the Library of the Chemical Society, arranged according to subjects with indexes containing authors' names and subjects, will be useful to chemists.

VOL. I. of "Studies from the Biological Laboratories of the Owens College" (Manchester: Cornish) is mainly a reprint of papers that have appeared in various journals.

WE have received the last (19th) Report of the Peabody Institute of Baltimore. There is no marked advance over past years in any department, but all have been prosperous and the results attained have been satisfactory. The attendance at the courses of lectures was exceptionally large, but the use of the library has been somewhat reduced owing to the opening of another free public library in Baltimore. Amongst the lectures during the year were courses on Arctic Explorations and Life in the Arctic Regions, on Mexico, Ancient and Modern, on the Mound Builders of Ohio, and on the Poetry of Science.

MR. C. G. ROCKWOOD, jun., of Princeton, N.J., writes that the shock of earthquake at Sandy Hook, New York, of June 11, noticed in NATURE of June 17 (p. 153) is an error. The tremor which was felt in that vicinity at the time stated, and which was at first reported as an earthquake, was afterwards traced to the firing of heavy guns on board the U.S.S. *Juniata*, at that time approaching Sandy Hook.

THE additions to the Zoological Society's Gardens during the past week include a White-handed Capuchin (*Cebus hypoleucus*) from Brazil, presented by Madam Sangiorgi; a Levaillant's Cynictis (*Cynictis penicillata* ♂), five Suricates (*Suricata tetradactyla* ♂ ♂ ♀ ♀ ♀), two Triangular Spotted Pigeons (*Columba guinea*), three Vinaceous Turtle Doves (*Turtur vinaceus*), two Cape Turtle Doves (*Turtur capicola*) from South Africa, presented by Mr. R. A. Fairclough; two Red Foxes (*Canis fulvus* ♂ ♀) from North America, presented by Messrs. Enson, Weber, and Co.; a Masked Paradoxure (*Paradoxurus larvatus*) from Hong Kong, presented by Mr. J. Orange; five Forster's Milvagos (*Milvago australis*) from the Falkland Islands, presented by Mr. James Moore; a Tawny Owl (*Syrnium aluco*), British, presented by Master C. G. Gregory; five Common Toads (*Bufo vulgaris*) from the South of France, presented by Mrs. F. Walker; a King Vulture (*Gypagus papa*) from Brazil, deposited; three Lions (*Felis leo* ♂ ♀ ♀) from Africa, a Grey Squirrel (*Sciurus cinereus*), a Mink (*Putorius vison*), three Hudson's Bay Squirrels (*Sciurus hudsonius*), a Virginian Eagle Owl (*Bubo virginianus*) from North America, purchased; two Mule Deer (*Cariacus macrotis* ♂ ♂), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *AUGUST* 1–7

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 1

Sun rises, 4h. 26m.; souths, 12h. 6m. 4·9s.; sets, 19h. 46m.; decl. on meridian, 17° 59′ N.: Sidereal Time at Sunset, 16h. 27m.

Moon (one day after New) rises, 5h. 59m.; souths, 13h. 19m.; sets, 20h. 26m.; decl. on meridian, 11° 23′ N.

THE VOLCANIC ERUPTION IN NEW ZEALAND

FURTHER details have been received of the volcanic eruption in the Hot Lake district of New Zealand, which has been the scene of a terrible and unexpected catastrophe which

occurred early on the morning of June 10. At Ohinemutu, on Lake Rotorua, the earth began to tremble at midnight. At ten minutes past 2 a.m. there was a heavy quake and a loud roaring noise which startled the inhabitants and caused them to flee from their houses. From this point it could be seen that Mount Tarawera, about fourteen miles distant, had suddenly become an active volcano, belching out fire and lava to a great height. At 4 a.m. a dense mass of ashes poured down, accompanied by suffocating smells. A large black cloud, which extended in a line from Mount Tarawera to the Pairoa Mountains, was filled with flame and electricity. The thunder-like roar from the crater, the sulphurous smells and constant quaking of the earth, caused many of the inhabitants to leave their homes and proceed to Tauranga, a distant township on the east coast. At 8 a.m. the aspect of affairs was as bad as it was all night, and hundreds of boiling springs had broken out around Lake Rotorua. At 11 a.m. the eruptions were going on continuously, and all the country down to Tauranga was in total darkness, with thick clouds of dust and sulphurous fumes in the air. At one o'clock the darkness had all cleared away and the principal centres of eruption had subsided.

At Lake Taupo, about forty miles to the south of Tarawera, the spectacle presented was most extraordinary. At 2 a.m. the outbreak was heralded by terrific reports, which resembled the roar of artillery, while a pillar of flame shooting hundreds of feet into the air was observed in the locality of the eruption. A great black cloud hung over this pillar, whilst flashes of electricity shot out from the cloud in every direction, shedding an unearthly bluish light. Loud reports, accompanied by heavy shocks of earthquake, followed in quick succession, and kept on until six o'clock, when the daylight and clouds of ashes rendered the sight invisible.

At Tauranga, forty-seven miles distant to the north-east, loud reports of heavy earthquakes began at 2.15 a.m., and very severe shocks were experienced at 3 a.m., while in the direction of the outbreak the country was illuminated for hours with flames and lightning. In the neighbourhood of Maketu, fifty miles to the east of the principal centre of eruption, atmospheric disturbances caused darkness till 10 a.m., and the shocks of earthquake were accompanied with strong lightning and earth currents, while at Hamilton, eighty miles to the west, the volcanic discharges are said to have resembled the firing of great guns at sea.

The devastation caused by the eruption is very widespread, and it is believed that all the natives round Rotomahana and Tarawera Lakes must have died. About a hundred Maoris are known to have perished. Mr. Haszard, the schoolmaster at Wairoa, and his four children and niece, and an English tourist named Bambridge are the only Europeans known to be killed. The country for fifty miles around the vicinity of the disturbance has been covered by the discharge of stones and ashes, and large craters have risen up. Mount Tarawera is elevated 300 feet higher than before. Lake Rotomahana has subsided, and has been transformed into an expanse of seething mud, and the renowned terraces are reported to be destroyed. Large areas are covered with volcanic dust and mud. During the disturbance the wind blew from the east, heavy snow fell on the ranges, and there was intense cold.

The wide area forming the scene of the eruption has been the chief centre of volcanic activity in New Zealand since the country has been known to Europeans, and in fact since the earliest period of Maori tradition. The region forms of itself a distinct volcanic zone remarkable for its picturesque hot lakes, boiling geysers, and numerous thermal springs. For many years it has been the resort of tourists from all parts of the world, and who reached it by way of Tauranga, a picturesque town on the east coast of the North Island, with a fine harbour opening into the Bay of Plenty. It is in this bay, about 30 miles from the mainland, that the first indication of volcanic activity presents itself in the form of Whakari, or White Island, a cone-shaped mountain which rises abruptly from the sea to an altitude of 860 feet. The crater, about $1\frac{1}{2}$ miles in circumference, is in a condition of a very active *solfatara*, whose numerous geysers and boiling springs evolve at all times dense volumes of steam and sulphurous gases.

From Tauranga the traveller proceeds in a southerly direction through a fern-clad country interspersed with broad belts of primæval forest presenting the most luxuriant and varied vegetation. In a distance little short of 40 miles the land rises gradually to an altitude of 800 feet, when the great table-land of the Lake Region is reached. Here, in a depression which appears to have formed at some remote period the area of an immense lake-basin, is situated the township of Ohinemutu, where there are several good hotels and a small white population. Just beneath the township the blue surface of Lake Rotorua, with the picturesque Island of Mokoia in its centre, spreads itself out in a circle of nearly 25 miles. The area in the immediate vicinity of the lake, where the action of the thermal springs is most active, extends from Whakarewrewa on the one side to Te Koutu on the other, and inland to Tikitere and Ariki Kapa, celebrated for its big holes of black boiling mud. Hot springs occur on its southern shore, while still further to the east of it again are the warm lakes known as Rotorua and Rotoehu. The native settlement is situated on a long peninsula stretching out into the waters of Lake Rotorua. Every part of this strip of land is dotted and riddled with thermal springs, some of which shoot out of the ground from small apertures, while others assume the forms of large steaming pools. They are of all degrees of temperature from tepid heat to boiling-point. Here the *whares* or huts of the natives are clustered promiscuously about the springs, and in situations where a few inches below the surface the soil is sufficiently hot to cook an egg in a few minutes.

It is this region which may be said to contribute the first link in the chain of active thermal action, extending from Whakari in the Bay of Plenty, through the Lake Country, to the active volcano of Tongariro, in the centre of the island, a distance in a direct line of about 130 miles.

At a distance of about nine miles still southerly from Lake Rotorua, lies Lake Tarawera, with its cluster of minor lakes, which constitute the second and most important connection in the volcanic belt. It was here the recent volcanic disturbance first declared itself in the sudden activity of Mount Tarawera, an extinct volcanic cone which had remained quiescent since time immemorial.

No place in the world could boast of scenery so unique and thermal phenomena so marvellous as could Tarawera and its surroundings. It was reached from Tarawera by a delightful route fringed by fern-clad mountains, and through the Sikitapu Forest one of the grandest gardens of primæval vegetation in New Zealand, but which is now uprooted by the force of the subterranean devastation. At the southern exit of the forest the traveller was charmed by Sikitapu, the Blue Lake, and Rotokakahi, the Green Lake, whose calm picturesque beauty formed one of the grandest sights of this singularly gifted region. A few yards from this point nestled the native settlement of Wairoa, now covered with 10 feet of ashes. Here were two hotels for the accommodation of tourists, who came from places far and wide to visit the wonders of the Terraces. From time out of mind it had been one of the principal homes of the great Arara tribe, who claim to be the pioneers of the race in New Zealand.

Down a wild gorge from Waira Lake Tarawera lies embosomed in a circle of tall forest-clad mountains, whose pointed peaks and serrated ridges betoken at once their Plutonic origin, while on the southern shore of the Lake rises Mount Tarawera, in the form of a colossal truncated cone, with pointed peaks like a spiked crown. It was out of this giant mountain *tapu*, and sacred in Maori song and legend, that the recent subterranean fires first shot forth, enveloping the whole mountain in a sheet of flame.

A glance at this mountain and the surrounding region was sufficient to show that at some remote period it must have been —as now—the chief centre of a widely-extended volcanic action. The mountain itself formed one of the principal volcanic cones to be found dotted over the country. A range of volcanic hills sloped down on its western side to Lake Rotomahana, which was connected with Lake Tarawera by a small warm stream known as Te Ariki. Before the eruption occurred the shores of the former lake formed the principal point of thermal activity in the district, and there can be little doubt that beneath its surface the forces which culminated in the outbreak of Mount Tarawera were evolved.

Lake Rotomahana, now said to be nothing more than a hole of seething mud and vaporous gases, formed in reality the wonderland of the region. Like Lake Tarawera, it was situated at an elevation of a little over 1000 feet above the level of the sea. It was one of the smallest of the group of lakes, being about a mile long by a quarter of a mile wide. It was, however, grandly picturesque, not only by reason of its unequalled features presented by the terraces, but likewise on account of

its steaming shores with their countless hot springs, boiling geysers, steaming cauldrons, and seething mud-pools, as well as by the bold, rugged scenery which surrounded it on every side. The name Rotomahana in the native language means literally "hot lake." The mean temperature of the water was about 80° F., while in the vicinity of the hot springs it rose frequently to 212° F.

It was on either shore of this lake that the marvellous terraces now unfortunately reported to be destroyed were situated. The largest of these singular formations was Te Tarata, or the White Terrace, the outline of which assumed a semicircular form and spread out at its base as it sloped gently down to the margin of the lake; the broad, flat, rounded steps of pure white silica rose tier above tier white and smooth as Parian marble and above them terrace after terrace mounted upwards, rounded and semicircular in form. All were formed out of a delicate tracery of silica, which appeared like lacework congealed into alabaster of the purest hue; crystal pools shaped as if to resemble the form of shells and leaves, and filled to their brims with water blue and shining as liquid turquoise charmed the eye, while around the edges bright crystals of silica formed incrustations which made them appear as if set with a margin of miniature pearls. At the summit of the terrace was a crater of 200 feet in diameter filled to overflowing with brilliant transparent water in the form of a boiling fountain, from which clouds of steam floated constantly upward. This boiling spring formed an intermittent geyser, which during its active intervals threw up a column of water to a height of over 100 feet. The crater, however, was always overflowing, and the water, which was highly charged with silica, had by a gradual process of deposition, extending probably over a vast period, formed the present system of terraces. The temperature of the water varied from boiling point to 70° F. at the foot of the terrace, the summit of which was over 80 feet above the level of the lake.

Immediately at the back of the White Terrace and bordering the lake was a rocky desolate gorge seamed and furrowed in every direction with streams of hot water, while jets of hissing steam bursting from its sides marked the sites of subterranean fires. The high hills on each side of the gorge rose up in quaint fantastic shape, and their rugged sides composed of shattered volcanic rock sent forth water and jets of steam from a thousand fissures. Here boiling geysers emitting clouds of steam lashed their hot waves about and foamed with a furious sound in rock-bound basins, while scattered over the greater portion of this fiery wilderness were innumerable fumaroles all hard at work shooting out steam and vomiting black streams of liquid mud. Some of these were round, some flat, and others cup-shaped, while not a few assumed the form of miniature volcanoes.

It was opposite to this spot on the further shore of the lake, that Te Otukapurangi, or the "Fountain of the Clouded Sky" of the Maoris, or the Pink Terrace, rose from the water of the lake to an altitude of nearly 100 feet. Here the deposits of silica assumed the same general formation, and each terrace of steps was gracefully and marvellously shaped with rounded edges which swept about in waving curves. The various buttress-like masses which supported the fringed edges of the terraces bent over and formed miniature grottoes resplendent with festoons of pink-tinted silica and rose-coloured stalactites which appeared to have been woven together by nature into an intricate network and then crystallised into their present shape. Here the successive deposits or layers of silica-rock did not assume, like those of Te Tarata, a wonderful combination of delicate lacework around the edges of the terraces, but the siliceous laminations appeared even thinner, and reminded one of the corrugated surface of pink satin rep. It was, however, the variegated tints of this wondrous structure which rendered it even more remarkable than the gracefully symmetrical proportions of its incomparable design. As the blue-tinted water came rippling and falling from terrace to terrace in miniature cascades, Te Otukapurangi looked radiant in its sparkling mantle of delicate pink, and as the golden rays of the sun shot far and wide, it changed with every shade of light, with brilliant hues of pink, amber, carmine, and yellow, which shone with a dazzling and metallic lustre as they flashed and palpitated as it were in the warm glowing air.

At the summit of the terrace was a circular platform, in the centre of which was a steaming cauldron formed by an alabaster-like basin about 100 feet in diameter. Here the deep dark-blue water within a few degrees of boiling-point lay without a ripple upon its surface, and shone with the brilliancy of transparent crystal, while beneath the siliceous deposits, which encrusted the sides of the crater, assumed all the varied designs of a coral grove tinted in glowing colours of yellow, blue, and pink.

From Lake Rotomahana the recent volcanic eruption extended to the Pairoa Mountains, which attain to an altitude of 1000 feet, and which, when visited by Mr. Kerry-Nicholls, were hot, and quaking with internal fires, boiling mud pools, and coiling jets of steam that burst with a hissing sound from the deeply-scarred hills. The base of this range, where the volcanic action was greatest, was formed of a burnt fiery-looking earth, broken here and there into enormous fissures, and dotted about with boiling pools and deep holes of hot seething mud, while clouds of vapoury steam burst forth from the highest peaks.

Following up the line of thermal activity across the island, as yet not known to be affected by the recent outbreak, hot springs and geysers are found at Orakeikorako on the banks of the Waikato and in various places along the whole valley of the rivers, and notably at Wairakei, where the thermal activity is both widespread and extraordinary in its variety. At Taupo, the great central lake of the island, geysers and other phenomena of the kind exist on its northern shores. From this point further across the lake the hot springs and geysers of Tokanu occur, while a short distance beyond rises the cone-shaped form of Tongariro, at an altitude of 7000 feet, the two craters which are in a state of very active *solfatara* constantly emit vast volumes of steam. Five miles to the south of the latter mountain rises the colossal form of Mount Ruapehu, which, with a base of over sixty miles, rises to an altitude of 6000 feet to the region of perpetual snow. This mountain, which was at one time the chief centre of volcanic activity of the north island, has been extinct from time immemorial, but it is reported that during the recent eruption steam was seen to issue from the crater. It is the highest point of the north island, and was ascended by Mr. Kerry-Nicholls and his interpreter, Mr. Turner, in 1883.

SCIENCE IN NEW SOUTH WALES

IN his Annual Address (on May 5) to the Royal Society of New South Wales, the President, Prof. Liversidge, referred to the death of Prof. Smith, the former President of the Society, and to the eminent services which he had rendered to the cause of science and of education in New South Wales, and also to other members of the Society who died during the past year. The President then expressed regret that the number of original papers contributed to the Society is so small. "It is not," he said, "from lack of subjects, for there are many questions which require investigation, but rather from the lack of competent investigators who can spare the necessary time. Up to the present but little original work has been done in working out the chemistry of the mineral and vegetable products, and but very little in many branches of biology. The descriptions, catalogues, lists, &c., of the flora and fauna, are making fair progress, but still very little has been published relating to the development and life-history of the fauna of Australia, even of forms of life peculiar to that part of the world. In matters of natural history, geology, and allied subjects it is apparent to every one that the materials for original work are in New South Wales abundant, and a considerable amount of very valuable work is being done in this direction by the Linnean Society of New South Wales, but the amount waiting to be done is far more than they can cope with at present. The Society, by offering a medal and a money prize, has done what it can to stimulate research; but the amount at its disposal is small. So many subjects if thoroughly worked out would be of economic value to the colony—such as the chemistry of Australian gums and resins, the tin deposits, iron ores, and silver ores of New South Wales —that the Government might with propriety assist the Society in undertaking these researches. Wealthy colonists might also, with advantage to the State and credit to themselves, encourage such original investigation." Speaking of biological work, the President said that one of the few facilities for scientific work possessed in Sydney, and which the Society assisted in founding, viz. the biological laboratory at Watson's Bay, has been closed, the Government having taken the house and grounds for defence purposes. The trustees will doubtless receive the cost of the buildings, and with this as a nucleus a fresh start can be made. It would be a great pity to allow such an undertaking to drop, especially as there is such an unlimited field for marine biological work in Australia. In regard to scientific education

in the colony, Prof. Liversidge said that notwithstanding the liberality of Parliament and the receipt of private endowments for improved instruction in science, many of the arrangements for this purpose of the Sydney University are of a very meagre and imperfect character. The Board of Technical Education is now doing good work in spreading elementary, scientific, and technical education over the colony by means of science classes and itinerant lecturers. The necessity of scientific education is also being recognised; there is a motion before the Legislative Assembly to place the sum of 10,000*l.* upon the estimates for the establishment of schools of mines in the various mining centres, while another motion to be brought proposes to make provision for the creation and endowment of twenty scholarships of the value of 200*l.* per annum, each tenable for three years, at the Sydney University. The President then referred to Prof. Huxley's remarks in his anniversary address to the Royal Society on scientific federation. Prof Huxley said:—"I have often ventured to dream that the Royal Society might associate itself in some special way with all English-speaking men of science; that it might recognise their work in other ways than by the rare opportunities at present offered by election to our foreign fellowship, while they must needs be deprived of part of its privileges." On this Prof. Liversidge remarks that though every one will agree as to the desirability of having closer bonds of union between the Royal Society and the men of science who are scattered over the wide areas of English-speaking countries, it does not appear easy to suggest a method of bringing it about. Good work in the Colonies, at any rate at present, is rarely overlooked by the Council of the Royal Society. Prof. Liversidge concluded his interesting address by suggesting a federation or union of the members of the various scientific societies in Australia, Tasmania, and New Zealand nto an Australasian Association for the Advancement of Science, on the lines of the British Association, with a view to holding the first general meeting in Sydney on the hundredth anniversary of the founding of the colony. A meeting of the kind during the centennial year would offer a unique opportunity for the exchange of ideas and information, and it would not only have an immediate and beneficial effect, but would permanently raise the high-water mark of thought in all the colonies, especially in connection with scientific matters. It would be an opportunity to correlate and correct all the scattered and fragmentary geological maps and memoirs relating to the various colonies, and to adopt a uniform system of nomenclature, colouring, &c., for all Australasian geological maps. It would, pursued the President, be beneficial if botanists were to prepare and revise the census of plants for each colony, especially to show their distribution, and similar questions could be discussed by zoologists for land and marine organisms.

ICE MOVEMENTS IN HUDSON'S BAY[1]

In my report last year I described the ice as consisting of three kinds, viz., icebergs, heavy arctic ice and ordinary field ice. The icebergs are stated to have come from Fox Channel. This conclusion was based on the report from No. 3 station made on the homeward voyage of the *Neptune*, that the icebergs passed the bluff from west towards east. This report was made on the strength of the few observations which the party had been able to make in the interval between the two calls of the *Neptune* at the inlet. Further and more perfect observations show conclusively that the current sets in the opposite direction and that the icebergs move from east to west. If further proof of the existence of this set were necessary, we have it in the drift of the *Alert* when fast in the ice off Ashe Inlet and invariably carried to the westward.

In considering the question of the sources from which the ice affecting Hudson's Straits navigation comes, we must first begin with the east Greenland ice. All those who have made the voyage from any port in Europe to Hudson's Straits seem to agree in the statement that Cape Farewell must not be approached nearer than seventy miles in order to keep clear of the east Greenland ice which sweeps round the cape in an almost ceaseless stream, after rounding which it turns to the northward, and passes up the south-west shore of Greenland, nearly as high as Gothaab, then turns over to the west side of Davis' Straits, and joining the stream of Davis' Straits ice runs south with the arctic current. The limits of the east Greenland ice field, when rounding Cape Farewell, vary greatly; in some years, it moves as far south as the parallel of 58° N. This ice field can be, and is of course always avoided, the rule in making the passage being to keep to the south of 58° N. till in longtitude 58° W., on which meridian the northing should be made.

The stream of Davis' Straits ice flows right across the entrance to Hudson's Straits, and varies in width with the season of the year. The first information which I have of it was derived from conversation with Captain Watson, of the whaling barque *Maude* of Dundee, owned by Captain Adams. Captain Watson had been for many years engaged in the Davis' Straits whale fishing, and for the last few years has commanded his present vessel. Their usual routine is to leave Dundee in March, and they arrive off the edge of Davis' Straits ice in the early part of April, cruising off the edge of the ice between latitudes 58° N. and 63° N. Captain Watson told me, that he made the ice in April of this year about 58° N. and 120 miles off the Labrador coast, and up to the date of our meeting with him, June 13, he had not been able to get nearer to Resolution Island than thirty-five miles, and as the average southerly set of the current is about twenty miles per day, this stream of ice must have been flowing uninterruptedly up to June 15, the date on which the *Alert* took the pack. An examination of the records of the stations at Port Burwell and Nachvak Bay shows that at Port Burwell the ice cleared out of the Straits on April 9. They remained clear up to the 14th, when the ice came in sight again, and was present almost constantly thereafter until its final disappearance in August. At Nachvak the ice swung on and off the shore with the winds and tide, but though sometimes out of sight from the ordinary observation point, it was always seen upon going to a higher elevation. It is therefore certain that during the months of May, June, and July, large fields of ice were present in the entrance of the Straits, and the question remains, at what date was this ice in such a condition as to permit the passage of vessels strengthened for meeting the ice, but which could be used as freight steamers. For in all questions as to feasibility of the navigation I am not considering the date at which one of the Dundee whaling or Newfoundland sealing steamers could be forced through, but when a strongly built iron steamer, sheathed and otherwise strengthened, could make the passage.

On June 15, when we went into the ice, it was certainly impenetrable by any vessel of the class referred to, and though the ice would slacken at the turn of every tide, and sometimes run abroad so that it would have been possible to work the ship to the westward, distances varying from two to five miles at each of these slack times, I only tried to hold my own, generally under canvas; as apart from any question of the injury which the ship had received, I deemed it more desirable to watch the ice at the entrance of the Straits than to force the ship through, when I could only have made at the most ten to twenty miles a day. I am of opinion that the Straits were passable at the eastern entrance about the date that we returned to St. John's for repairs, viz., July 5, but any ship going in at this date would still have been subject to these delays, but might have made from twenty-five to forty miles a day.

Proceeding westward, from this date, July 5, the observations at Ashe Inlet and Stupart's Bay show that on the north side of the Straits, and from eighteen to twenty miles out, the ice was present almost continuously, much as we found it in August; some of the sheets of enormous extent and of great thickness. Many of these were, in August, over half a mile long, and some which we measured were from twenty to thirty feet in thickness. In the middle of July, Mr. Ashe reports that open water is visible beyond the ice, and Mr. Stupart, fog-banks and water sky frequently to the north. The two stations at the western end of the Straits also report that in the middle of July the ice was loose and drifting with the tide. Everything goes to show that though there would have been very frequent delays still it would have been possible for a steamship to have got through the Straits by July 15 or 20.

Ice would have been met with again, doubtless, in the bay, but I do not think there would have been any serious delay in reaching either Churchill or York Factory.

Stations on shore for the purpose of watching the movements of the ice, though undoubtedly the best system which we can adopt, cannot tell us with any degree of certainty how soon a vessel might be able to push her way through the Straits, but they do tell when it is sufficiently run abroad, or

[1] From the Report of the second Hudson's Bay Expedition under the ommand of Lieut. A. R. Gordon, R.N., 1885.

when a sufficient amount of open water appears, to make the passage a reasonable certainty, and the date for this year I place at from July 5 to 15, as it is more than likely that a ship could have got through the Straits in ten days. The ice is, moreover, so sensitive to wind that even if telegraph stations were so placed as to be able to convey to ships news regarding the position of the ice ahead, long before the vessel arrived at the place the condition of affairs might, and probably would, be totally changed.

As to the closing of navigation in 1884, Mr. Laperrière reports, at Cape Digges, that on October 25 the ice was solid in every direction, and at Nottingham Island a similar entry is made on the 27th. A distinction must be made between the closing of navigation by the formation of young ice, and the presence of a large field of heavy old ice which is cemented together by the formation of young ice between the pans. In the first case any ordinarily powerful steamer could go through without risk, but in the second case the most powerful of the whaling or sealing steamers would be helpless. The western end of the Straits is always subject to incursions of this heavy ice, from Fox Channel, and especially so in the months of September and October, when strong north-easterly and north-westerly gales are frequent, and we have now evidence that in both seasons, 1884 and 1885, this heavy ice came down in October.

As to the length of season for practical navigation, if we regard the presence of field ice as the only barrier, the information which we have got would point to the months of July, August, September, and October as being the months in which the Straits are passable. As a rule, in July there will be delays, but to vessels strengthened and sheathed there would be no danger in making the passage.

All the inhabitants of the Labrador, the Straits, and the Bay, spoken to on the subject, agreed in stating that the ice movements this year were much later than the average; at Fort Churchill the season was fully a month late, and on the Labrador three weeks, so that I think it will be found that on the average four months will be the length of the season for practical navigation by steam vessels which would be freight-carriers. There have been, I am informed, seasons when the Straits were clear of ice in the month of June, but they are, according to the logs of the Hudson's Bay ships, quite exceptional. Captain Hawes spoke of such being the case only once in his experience of fourteen years, and the dates which I have seen of the arrival of the Hudson's Bay vessels at their ports of destination show no arrival earlier than August.

THE TRANSCASPIAN FAUNA

WE notice in one of the last issues of the *Bulletin* of the Moscow Society of Naturalists (1885, No. 2) a most valuable paper, by M. Zaroudnoi, on the birds of the Transcaspian region. His list contains an enumeration of 184 species, well determined on 600 specimens—doubts remaining only with regard to a very few species. The author distinguishes in the region the following chief zoological sub-regions:—(1) The Kara-kum desert, having a pretty well furnished flora, notwithstanding its immense sandy plains and salt clays. The Tamarix forests, now mostly destroyed, are well peopled with the *Atraphornis aralensis*, as also with a few *Podoces* (*Panderi?*) and *Passer* (*ammodendri?*), which make their nests further north in the *saksaul* forests. The *Houbara quennii*, Gray, is rare. The reptiles are represented by the *Phrynocephalus interscapularis* and *helioscopus*, *Agama sanguinolenta*, *Testudo*, *Naja oxiana*, Eichwald; the *Varanus scincus* extends much further south into the Akhal-Tekke plain, and even to the Kopet-dagh Mountains. (2) The Akhal-Tekke oasis, striking by the monotony of its landscape, diversified only by the gardens of the Tekkes, which remain green even during the hottest part of the summer, when all vegetation is scorched up by the sun. In the plain only the Tamarix, a few willows on the banks of the rivulets, and the dark-green bushes of the capers, adorned with pretty flowers, are to be seen. The great areas covered with bushes of *Alchagi camelorum* and wormwood increase the monotony of the landscape. Pretty *Julodis variolarius*, *eufraticus*, and sometimes *globicollis* are often found flying around these bushes; in July the *Fisheria baetica*, Ramb., several Irises, as also *Empus pennicornis*, Pall., several kinds of *Ateuchus* and *Copris*, and numerous species of *Melanozomatæ* are met with. The stone-chatters (traquets) and larks are so numerous as to become troublesome. The *Phrynocephalus helioscopus* and *Agama sanguinolenta* fly at the approach of man. From time to time a *dscheiran*, or a fox, may be perceived. The nights are sultry and hot, and one hears the shrivelling of the *Grillus cerisyi*, Serv., and *G. capensis*, Fabr., the barking of the jackals, and the cries of *Caprimulgus arenicolor*, Sev. The banks of the few rivers, covered with brush and reed-grass, are the refuge of the wild cat and the *Lagomys*. The high summer temperature of the oasis is well known: 40° Cels. in the shade being not uncommon; and M. Zaroudnoi is inclined to ascribe to the great heat the intensity of the moulting of birds. The lark loses so much of its feathers that the body remains in many parts quite naked; with the stone-chatters only the base of the feathers remains on their heads. Most of the birds met with in the oasis during the summer belong to the Aral-Caspian fauna, the others come from the mountains; these last have followed the courses of the rivers and have taken possession of the Akhal-Tekke gardens; such are the *Salicipasser montanus*, *Passer indicus*, *Sylvia mystacea*, *Butalis grisola*, a great number of *Salicicariæ*, and several others. Some, like the griffons, the ravens, the *Cypselus apus*, the *Chelidon urbica*, the *Merops apiaster*, inhabit the mountains, and descend to the plain only for hunting. The *Galerita magna*, *Calandrella pispoleta*, and *Saxicola isabellina*, may be considered as representatives of the Akhal-Tekke fauna owing to their considerable numbers. (3) The mountain-region is much more interesting, especially when the traveller reaches the upper valleys covered with forests, where the vines grow wild. Wild cats and jackals are the usual inhabitants of these valleys; but the *Cynailurus jubatus* and the *Leopardus pardus* are rare; *L. irbis* is never met with in the region. *Hyæna striata* is occasionally met with. *Ellobis talpinus*, several *Erinaceus* and *Platycercomys*, as also *Histrix hirsutirostrix* are common. The dreadful *Vipera eufratica* is a source of continual danger during the grape-harvest. *Eremias velox* and *Agama sanguinolenta* are worthy of notice. As to the birds, we must merely refer to the list of M. Zaroudnoi, where notes as to their distribution are given in French. The zoological determinations have been revised by M. Menzbier.

SOCIETIES AND ACADEMIES

London

Royal Society, May 27.—"Researches in Stellar Photography." By the Rev. Prof. Pritchard, F.R.S.

The objects of these researches are:—(1) To ascertain, if possible, by means of definite and accurate measurement, as distinguished from impressions and estimates, what is the relation between the diameter of a star-disk impressed on a photographic plate with a given exposure, and its photometric magnitude, instrumentally determined. With this view, five plates of the Pleiades were taken with different exposures, on different nights. The diameters of the star-disks on each of the plates were then measured with a double-image micrometer, checked by measurement also with the macro-micrometer in the Oxford University Observatory. Curves were then drawn for each of the plates, taking the magnitudes as given in the "Uranometria Nova Oxoniensis" as abscissæ, and the measured diameters as ordinates. The result was a satisfactory coincidence in the case of all the plates, leading, when treated in the usual manner, to the final result—

$$D - D' = \delta \left\{\log M' - \log M\right\} \quad . \quad . \quad . \quad (1)$$

where D, D' are the measured diameters of any two stars on the plate, and M, M' the corresponding photometric magnitudes; δ being a definite constant depending on the physical circumstances of the particular plate.

It was observable that, out of twenty-eight stars examined, three stood out from the rest, indicating, as might have been expected, some peculiarity in the spectra of these stars. In the memoir itself the tabular relations of all the measures are exhibited. The similarity of the symbolical form above to the relations existing between "magnitude" and intensity of light is obvious and interesting.

(2) Another branch of the inquiry is still more important, and it is this. Seeing that in the modern use of the dry plates the times of exposure are so considerable, and the processes of development and drying, &c., so suspiciously dangerous to the stability of the films, it becomes a matter of great importance to ascertain

whether the photographic plate remains an absolutely accurate picture of the actual relative positions of the stars in the sky itself, and, moreover, whether these are measurable with that extreme degree of precision which is attainable with the best instrumental means. To ascertain this, the same plates for a portion of the Pleiades were taken which gave rise to the formula already obtained. The distances of some twenty-five of the stars from Alcyone were measured on each of these plates, the number of repetitions of the measures being made the same as those adopted by Bessel in his measures of the same distances with his heliometer. The resulting accordances of these individual measures on each of the plates was very satisfactory, and a trifle better than the accordances in the case of Bessel's measures; and the accordance of each of the means of the distances of each of the stars from Alcyone on each plate was at least quite equal to the results obtained with the heliometer. The average deviations from the mean for all the measures was, in the case of the photographic plates, 0''·24, and, of the heliometer measures, 0''·29. These satisfactory accordances of the resulting measures on each of the plates (corrected for refraction, and where necessary for aberration), afford a sure indication of the reality of the pictures, as well as of their accurate measurability.

An interesting circumstance occurred in the course of the work. On one of the plates the distances of three stars from Alcyone exhibited a slight discordance of from 0''·75 to 1''·5, when compared with those stars on the other plates. These three stars all occupied a small area on the plate; no discordances occurred on this plate with respect to any of the other stars. Here is an indication of a slight disturbance of the film on one small portion of the plate, but on no other portion. Hence the necessity of the precaution of taking at least three plates for the purpose of security of measurement. The plates were exposed variously for about 8 to 12 minutes in the focal plane of the de la Rue reflector of 13 inches aperture.

(3) A few stars were examined on the same plate with different exposures, varying from 1 second to 120, with the view of ascertaining, if possible, the relation between the areas of the impressed star-disks and their time of exposure. As far as at present appears, these areas vary as the square root of the time. This result differs widely from that obtained by Bond in 1858. That astronomer considered that these areas varied directly as the time; the investigation, however, is not yet complete, and will be resumed at Oxford. It is well known that these photographic disks are not sharply and definitely cut circles on the negative plate, when examined with the higher powers of the microscope, such as 100 and beyond; but they are fringed with a number of discreet black dots extending to some distance beyond the hard photographic images. Nevertheless, these images, when printed in the form of position, lose this fringe, and present the appearance of well-defined sharply-cut circles; the light appears to have penetrated through the interstices of the discrete fringe, and leaves a very definite outline. Encouraged by these results of the measurements of the stars from Alcyone, I propose to test this photographic method still further by applying it, not without hope of success, to the question of stellar parallax.

These measures are now well advanced, and afford good hope of success.

Chemical Society, June 17.—Dr. Hugo Müller, F.R.S., President, in the chair.—The following were elected Fellows of the Society:—Thomas Akitt, James Blake, M.D., Alfred Chaston, A. W. H Chapman, Augusto Cæsar Diojo, Charles A. R. Jowitt, Charles Alexander Kohn, John Temple Leow, William Ray, Joseph Price Remington, William Richards, Forbes Rickard, William Saunders, Charles A. Smith.—The following papers were read:—The electrolysis of aqueous solutions of sulphuric acid, with special reference to the forms of oxygen obtained, by Prof. H. McLeod, F.R.S.—Essential oils (Part III.): their specific refractive and dispersive power, by Dr. J. H. Gladstone, F.R.S.—The formation and destruction of nitrates and nitrites in artificial solutions and in river and well waters, by J. M. H. Munro, D.Sc.—Water of crystallisation, by W. W. J. Nicol, M.A., D.Sc., F.R.S.E.—A method of investigating the constitution of azo-, diazo-, and analogous compounds, by R. Meldola, F.R.S., and F. W. Streatfeild.—The estimation of free oxygen in water, by Miss K. I. Williams and Prof. W. Ramsay.—Note as to the existence of an allotropic modification of nitrogen, by Miss K. I. Williams and Prof. Ramsay.—The presence of a reducing agent, probably hydrogen peroxide, in natural water, by Prof. Ramsay.—Evaporation and dissociation (Part IV.); a study of the thermal properties of acetic acid, by W. Ramsay, Ph.D., and Sydney Young, D.Sc.—Note on the vapour-densities of chloral ethyl-alcoholate, by William Ramsay, Ph.D., and Sydney Young, D.Sc.—The nature of liquids as shown by a study of the thermal properties of stable and of dissociable bodies, by William Ramsay, Ph.D., and Sydney Young, D.Sc.—The electromotive forces developed during the combination of cadmium and iodine in presence of water, by A. P. Laurie, B.A., B.Sc.—Detection and estimation of iodine, bromine, and chlorine, by M. Dechan.—The analysis of alloys and minerals containing the heavy metals, selenium, tellurium, &c., by Thomas Bayley.

Entomological Society, July 7.—Mr. J. Jenner Weir, F.L.S., Vice-President, in the chair.—Mr. S. H. Scudder, of Cambridge, Mass., U.S., was elected a Foreign Member of the Society.—The Rev. H. S. Gorham exhibited specimens of *Eucnemis capucina*, Ahr., a species new to Britain, discovered in June last in an old beech tree in the New Forest. He also exhibited specimens of *Cassida chloris*.—Dr. Sharp exhibited larvæ of *Meloe*, and read notes on their habits, and Mr. Saunders exhibited a specimen of *Halictus* infested with about thirty *Meloë* larvæ. Mr. Billups remarked that he had recently found forty-seven larvæ of *Meloë* on the body of a species of *Eucera*. Dr. Sharp said that he was of opinion that the operations of these larvæ were not the result of instinct, but were more like reflex actions: the instant the larvæ touched a suitable surface they clung to it. The discussion was continued by Prof. Riley, who disagreed with Dr. Sharp, and believed these larvæ were guided by instinct, as they showed a decided preference for particular hosts.—Mr. Jenner Weir exhibited a male of *Lycæna bellargus* and a female of *L. icarus*, which had been captured *in copulâ* by Mr. Hillman, and shown to the exhibitor at the time of capture. Mr. Weir also exhibited some specimens of *Lycæna* which he believed to be hybrids between *Lycæna bellargus* and *L. icarus*; and he further exhibited, on behalf of Mr. Jenner, four specimens of *Phosphænus hemipterus*, taken at Lewes.—The Rev. W. W. Fowler exhibited two specimens of *Chrysomela cerealis*, lately taken by Dr. Ellis on Snowdon; and also two specimens of *Actocharis Readingii*, found at Falmouth by Mr. J. J. Walker.—Mr. E. B. Poulton called attention to the fact that the larvæ of some Lepidoptera, if fed in captivity on an unusual food-plant, subsequently refused to eat their ordinary food-plant. He stated that he had observed this with the larvæ of *Pygæra bucephala* and *Smerinthus ocellatus*. Mr. Stainton, Mr. Fowler, and Mr. Goss made some remarks on the subject.—Mr. Elisha exhibited a series of bred specimens of *Geometra smaragdaria*.—M. Alfred Wailly exhibited a long series of silk-producing moths, including some remarkable hybrids between *P. cecropia* and *P. ceanothi*; and Prof. Riley and Mr. Weir made some observations on these hybrids.—Dr. Sharp read a paper on *Eucnemis capucina* (Ahr.) and its larva.—Mr. Dunning read a report on the subject of the importation of humble-bees into New Zealand, from which it appeared that the efforts of Mr. Nottidge, of Ashford, and the Canterbury (N.Z.) Acclimatisation Society had been successful, and that the long wanted clover-fertiliser had at length been established in New Zealand.—M. Peringuey communicated notes on some Coleopterous insects of the family *Paussidæ*.—Mr. J. B. Bridgman communicated additions to the Rev. T. A. Marshall's Catalogue of British Ichneumonidæ.—Prof. Riley read notes on the phytophagic habit, and on alternation of generation, in the genus *Isosoma*. In this paper Prof. Riley described, from direct observation, the phytophagic habit in two species of the genus. He also established the existence of alternation of generation.

EDINBURGH

Royal Society, July 5.—The Hon. Lord Maclaren, Vice-President, in the chair.—In a paper on the electrical resistance of nickel at high temperatures, Prof. C. G. Knott, of Tokio University, gave an account of experiments on certain nickel wires, in which the temperature was carried to a fairly bright red head. The resistance at different temperatures was compared with the resistance of a platinum wire at the same temperatures; and, by the substitution of other metals for the nickel, further comparisons were established. Nickel, platinum, palladium, and iron were thus studied; and the general conclusions were as follows:—(1) The rate of growth of the resist-

ance of a given nickel wire with temperature is greater, on the average, than the corresponding quantity for platinum or palladium, and less than that for iron. (2) The "logarithmic rate"—that is, the rate of change per unit rise of temperature of unit resistance at any temperature—falls off more slowly for nickel as the temperature rises to 200° C. than for platinum or palladium. (3) At about 200° C. the rate of resistance growth for nickel increases markedly, and continues practically steady, till about 320° C., when a sudden decrease occurs, and thereafter the resistance steadily increases at this diminished rate. In other words, between the limits of temperature specified, the slope of the resistance curve is much steeper than for any other. The same peculiarity is probably possessed by iron between the temperatures of a dull red and a bright red heat. (4) The peculiarity occurs (in each case) between the limits of temperature within which the striking thermo-electric peculiarity discovered by Tait also occurs. This peculiarity, which is most briefly described as an abrupt change in the sign of the Thomson effect, is not known to be possessed by any other metal. (5) There is thus a strong presumption that the Thomson effect in metals has a close connection with the mutual relations of resistance and temperature—at any rate in metals in which the Thomson effect is proportional to the absolute temperature (according to Tait's theory) the "logarithmic rate" of change of resistance seems to be very approximately inversely as the absolute temperature. In nickel and iron, in which the law of the Thomson effect is peculiar, such a simple relation between resistance and temperature does not hold.—Prof. Tait discussed the effect of external forces on a system of colliding spheres. He gave a proof, much more simple than Maxwell's, of the fact that gravity has no effect in altering a uniform distribution of temperature throughout a vertical gaseous column. His proof is founded on the assumption that, in a horizontal layer of gas which has arrived at a steady state, all particles passing across the upper surface do so on the whole as if they had freely passed through the layer.—Dr. John Murray read a paper by Dr. H. B. Guppy on the mode of formation of the coral reefs of the Solomon Islands. In this paper the typical reefs were described with the various corals growing on them. In places exposed to the full sweep of the trade-winds the corals do not grow higher than to about 7 or 10 feet from the surface. In sheltered places they are found at a depth of from 4 to 5 feet. Dr. Guppy believes that the reefs never rise to the surface without upheaval. He gives a theory of the construction of barrier reefs, which corresponds to that formerly given by Le Comte to explain the reefs of Florida.—Mr. J. T. Cunningham, of the Scottish Marine Station, read a paper on the eggs and early stages of some teleosteans, and also a paper on the reproductive organs of *Bdellostoma*, and a teleostean egg from the West Coast of Africa.—Mr. Patrick Geddes gave a synthetic outline of the history of biology, and also read a paper on the theory of growth, reproduction, heredity, and sex.

Sydney

Linnean Society of New South Wales, May 26.—Prof. W. J. Stephens, M.A., F.G.S., in the chair.—The following papers were read:—Notes on some Australian Tertiary fossils, by Capt. F. W. Hutton. In this paper, which is based on the examination of a fine collection of Australian Tertiary fossils recently sent to the Canterbury Museum by Prof. Tate of Adelaide, Capt. Hutton enumerates seventeen species of molluscs and echinoderms which are common to the Tertiary strata both of Australia and New Zealand, and deals with their synonymy.—On some further evidences of glaciation in the Australian Alps, by James Stirling, F.L.S., communicated by C. S. Wilkinson, F.G.S. After reviewing what has been written on the subject of glacial action in Australia, the author adduces fresh evidence in favour of such action, obtained by himself and Dr. Lendenfeld during a recent visit to Mount Bogong, the highest mountain in Victoria, where erratics, perched blocks, smoothed surfaces, and old moraines were met with.—Jottings from the Biological Laboratory, Sydney University, by W. A. Haswell, M.A.: (No. 7) On a method of cutting sections of delicate vegetable structures; (No. 8) on the vocal organs of the Cicada.—Mount Wilson and its ferns, by P. N. Trebeck. Mr. Trebeck describes the position, geology, soil, and vegetation generally of Mount Wilson, and gives details of 15 genera of ferns, including 38 species, which were growing there in the greatest luxuriance from the very summit to a considerable distance down the slopes and gullies of the mountain.—List of the Rhizopoda of New South Wales, by Thomas Whitelegge. The list contains 24 species, with exact localities, and notes on collecting, preserving, and mounting Rhizopods. The species are mostly identical with those found in Europe, America, and India. Amongst those of interest the following may be mentioned:—*Arcella dentata*, Ehr., *Pelomyxa palustris*, Greeff, *Raphidiophrys elegans*, Hert. and Less., *Clathrulina elegans*, Ceinkowski, and *Biomyxa vagans*, Leidy.

Paris

Academy of Sciences, July 19.—M. Jurien de la Gravière, President, in the chair.—Remarks accompanying the presentation of M. de Saint-Venant's important manuscript memoir on "the resistance of fluids," by M. Boussinesq. This unpublished work, begun in 1847, and not completed till the year 1885, a short time before the author's death, embodies historical, physical, and practical considerations regarding the problem of the mutual dynamic action of a fluid and a solid, especially in the state of permanence supposed to be acquired by their movements. It comprises three parts, the first dealing with the researches of previous physicists on the impulse of fluids in motion on solid bodies encountered by them; the second showing theoretically that this impulse is connected exclusively with the "imperfection of the fluid," that is, the development of friction, which to be surmounted requires a higher pressure on the upper than on the lower surface of the submerged body; the third containing a practical calculation of the impulse experienced by a body in any indefinite fluid current.—On the displacement of ammonia by other bases, and on its quantitative analysis, by MM. Berthelot and André. It is shown that in the presence of soda the double salts yield their ammonia far less readily than the sal ammoniacs unassociated with another base; also that in the ordinary conditions of analyses magnesia is powerless to entirely displace the ammonia. With certain salts, such as ammoniaco-magnesian phosphate, the displacement is extremely slight or nil. These results must henceforth be taken into account in the analysis of earths and of other products containing organic matter associated with the phosphates or with magnesia.—On a reindeer's antler embellished with carvings found by M. Eugène Paignon at Montgaudier, by M. Albert Gaudry. This relic of the reindeer age ranks among the most interesting animal and human remains in recent years discovered by M. Paignon in the Montgaudier Caves, Tardoire Valley, Charente. It is pierced with a large hole and covered with carvings executed with such a sure hand and sentiment of form that it shows even to greater advantage under the magnifying glass than when viewed with the naked eye. One face shows two seals (*Phoca vitulina* and a larger perhaps of different species), a fish (a salmon or trout), and three twigs of plants. On the other side are two long slender animals, apparently eels, three other animal figures exactly alike but indeterminable, and an insect. This specimen of prehistoric art, of the authenticity of which there can be no doubt, has been presented by the finder to the Museum, together with several other objects from his valuable collection.—On the real position to be assigned to the fossil flora of Aix in Provence (continued), by M. G. de Saporta. The conclusion already arrived at on stratigraphic grounds, that this flora belongs to the triple series of the Upper Eocene, Tongrian, and Aquitanian, is here confirmed by the Palæontological indications themselves.—On the development in series of the potential of a homogeneous revolving body, by M. O. Callandreau.—On the variations of the absorption-spectra in non-isotropic mediums, by M. Henry Becquerel. Apart from certain anomalies here described, it may be generally assumed that for each absorption-band there is a single system of three principal rectangular directions, of such a nature that the intensity of a luminous vibration proceeding from a crystal parallel to the direction of the incidental vibration may be represented by the form $I = (a \cos^2 \alpha + b \cos^2 \beta + c \cos^2 \gamma)^2$, where α, β, γ indicate the angles of direction of the vibration with the principal directions, and a^2, b^2, c^2 the principal intensity of the radiation in question. This hypothesis seems to be confirmed by photometric measurements executed with plates of epidote.—On the decomposition of hydrofluoric acid by an electric current, by M. H. Moissan.—Note on urethane regarded from the standpoint of chemical analysis by M. Georges Jacquemin.—Action of some organic chlorides on diphenyl in the presence of the chloride of aluminium, by M. P. Adam.—On the normal propylamines, by M.

C. Vincent. The results of the author's researches are: (1) The separation of the three normal propylamines; (2) the discovery of nitrosodipropylamine; (3) the determination of the physical constants of di- and tripropylamine and of nitrosodipropylamine.—On a new creatinine (ethylamido-acetocyamidine), and on the formation of the creatinines and creatines, by M. E. Duvillier. From the author's experiments it follows, so far, that the action of cyanimide on the starch acids consists essentially in the formation of creatinines, that of creatines taking place only in a very few cases.—On a combination of stannic chloride with hydrochloric acid (chlorostannic acid), by M. R. Engel.—On the alcoholate of potassa, by M. E. J. Maumené. Referring to M. Engel's note in the last issue of the *Comptes Rendus*, the author points out that he had already determined and announced an alcoholate of potassa so far back as the year 1872 (*Les Mondes*, December 19, 1872).—Note on the antennæ of the Eunicians, by M. Et. Jourdan.—On the effects of pollinisation in the orchid family, by M. Léon Guignard. A series of experiments is described which the author has carried out for the purpose of determining the varying interval which intervenes between pollinisation and fertilisation in this group of plants.—On the amphibolic schists and gneiss, and on the limestones of Southern Andalusia, by MM. Ch. Barrois and Alb. Offret.—Fresh experiments with balloon photography: ascent of MM. A. and G. Tissandier and P. Nadar, by M. G. Tissandier. During this ascent, which took place on July 2, and lasted nearly six hours, the altitude never exceeding 1700 metres, M. Nadar took no less than thirty instantaneous photographs; of these about a dozen constitute undoubtedly the finest series of negatives yet obtained from a balloon. Amongst them were two views of Versailles at 800 metres; one of Sèvres at 600 metres; one of Ballème (Orme) at 900 metres; several perspectives of Saint-Remy (Sarthe), some at 1200 metres. During a second ascent the following week, M. Nadar secured three good views of Champigny and the banks of the Marne. These experiments place beyond all doubt the success of aërial photographic operations.

BERLIN

Physical Society, June 4.—Dr. Pringsheim spoke on a new application of the telephone for the measurement of electrical resistances, a purpose for which it had already been brought into use by Prof. Kohlrausch in cases in which the resistances were measured by means of alternating currents—in cases, that is, of fluid conductors and also in the case of wires. Dr. Pringsheim had, however, observed that in the measurement of wire-resistances by means of alternating currents the determinations by the telephone did not always concur with those of the galvanometer, and varied very much with repeated measurements. He therefore applied the telephone for measurement by means of a constant current, and that in the following manner. In the Wheatstone bridge the circuit usually occupied by the galvanometer was of constant resistance. The four sides of the wire arrangement contained the wire the resistance of which required to be measured, and the rheostat. The two free angles of the square were connected by a wire circuit in which was placed a telephone. So long as the resistances of the two sides of the bridge were not perfectly equal, a part of the current flowed through the telephone circuit, and each time this was opened a snapping was heard in the telephone. The rheostat resistance was then changed till nothing was heard on opening the telephone circuit. The sensitiveness of this method was equal to 0·04 per cent. of the total resistance.—Prof. von Helmholtz reported on his most recent investigations, which respected the "doctrine of the maximum economy of action," and communicated the interesting history of the understanding of this principle. The doctrine was first propounded by Maupertuis in 1744 in a treatise laid before the Paris Academy. This treatise contained, however, no general statement of the proposition, nor did it define the limits of its applicability, but only adduced an example. This example was, in accordance with the present state of our knowledge, not pertinent, and had no relation to the principle of the *actio minima*. Two years later Maupertuis propounded his principle before the Berlin Academy, proclaimed it to be a universal law of nature and the first scientific proof of the existence of God. On this occasion, too, he did not prove the proposition nor determine the limits of its applicability, but only supported it by two examples, one of which alone was correct. This principle, propounded with such grand solemnity, but so weakly supported, was violently attacked by König of Leipzig, and just as keenly defended by Euler. This mathematician likewise failed to furnish the proof, which was not possible till after the investigations of Lagrange. The form in which the principle of the *actio minima* now existed was given to it by Hamilton, and the Hamiltonian principle for ponderable bodies was in complete harmony with the Lagrange propositions. The elder Neumann, Clausius, Maxwell, and the speaker had already extended the Hamiltonian principle to electro-dynamics. For this purpose, and in order to be able to subordinate to it all reversible processes, the speaker had undertaken some transformations of it, and had introduced into it the conception of the "kinetic potential." In the form it had thus attained the Hamiltonian law—the old principle of the *actio minima*—had in point of fact universal validity. It had just as wide an application as had the law of the conservation of energy, and revealed a whole series of mutual relations between the different physical processes. In his communication Prof. von Helmholtz gave only a quite general view of his investigations.

THE BOOK OF DUCK DECOYS

The Book of Duck Decoys; their Construction, Management, and History. By Sir Ralph Payne-Gallwey, Bart. (London: John Van Voorst, 1886.)

IN the year 1812 appeared the first instalment of what its eccentric author intended to be a sketch of the local history of the Lincolnshire Fens; therein "Fen-Bill Hall" declares his set purpose of devoting a portion of the work to the "life of a low Fen-man," and of descanting largely upon the subject of decoys, adding that he had never seen but one rational writer on the subject, and that he (the said writer) manifested that he knew "nothing of the theory." Hall's book came to an untimely end with the third part, and the author therefore had not the opportunity of writing "rationally" upon a subject which would have proved so interesting in the present day and upon which so much irrational writing has been lavished. Failing "Fen-Bill Hall" so well did the decoymen keep their secret and so securely were the decoys guarded from intrusion that in all the numerous subsequent so-called descriptions, with one or two partial exceptions, the writers showed an utter want of acquaintance with both the theory and practice of decoying, and in the exceptional cases named such experience was of a very limited character, the deficiency being in all probability supplied by intentionally misleading information on the part of the guardian of the decoy. It was not till the year 1845, when the Rev. Richard Lubbock published his well-known "Fauna" of Norfolk, that the first really reliable account of the art of constructing and working a duck decoy, the result of actual experience acquired by the writer, was given to the public. Since that time various more or less accurate papers on the same subject have appeared, but it remained for Sir Ralph Payne-Gallwey (than whom no more competent authority could be found) to collect the literature of the subject, and with his own practical experiences added, to publish the first "Book of the Duck Decoy" in the form of the handsome volume now before us.

From very early times tunnel-nets appear to have been used for taking water-fowl, and there is no doubt much importance was attached to the privilege of using such engines, as appears from frequent litigation on the subject, dating back even as long ago as the reign of King John. These tunnel-nets were used for the purpose of securing young birds yet unable to fly, which with the old birds when moulting were *driven* into them. Sir Ralph Gallwey gives a curious woodcut of such an arrangement, as used in the sixteenth century, which represents in a somewhat diagrammatical way a phalanx of boats driving the birds before them into the nets fixed at the head of a bay, much as the Orkney fishermen drive a "school" of ca'ing whales on to the beach. This method of driving was found so destructive that it was prohibited by law, and was probably succeeded by a device called a cage-decoy, into which the ducks were enticed by feeding, and then secured by dropping a framework of netting which closed the entrance. Such a decoy is still worked at Hardwick Hall in Derbyshire, but it seems probable that decoys proper as used in the present day were not introduced into England till the commencement of the seventeenth century,—whether by Sir William Wodehouse as so often stated, on the authority of Sir Henry Spelman, Sir Ralph Gallwey appears to think doubtful. The decoy erected by Charles II. in St. James's Park in the year 1665 is doubtless the first arrangement on the Dutch plan for *alluring* ducks of which we have any exact account, and it is even possible that a curious old woodcut which occurs in a copy of "Æsop's Fables," dated 1665, and which Sir Ralph Gallwey reproduces at p. 9 of his book, may have been taken from this identical decoy; but should it, as seems more probable, have been sketched from a still earlier decoy, it would tend to prove that Sir William Wodehouse really had the honour of taking precedence of Charles II. in adopting the Dutch method of decoying.

For the successful working of a decoy a site must be chosen far from the busy haunts of men, secluded by a screen of trees, all the approaches to which should be under the control of its owners; at the commencement of the present century such spots were easy enough to find, and decoys abounded yielding large profits to those who worked them. Unfortunately very little is now known of the results of the working of these decoys, but we have it on the authority of Pennant that one celebrated group of ten decoys in Lincolnshire produced in a single year 31,200 ducks. There are also some published statistics of the Ashby decoy, showing that in thirty-five years 95,836 fowl were there taken; and a famous decoy in Essex produced in thirteen years 50,787 birds. Sir Ralph Gallwey estimates that 100 decoys which formerly existed in the Eastern Counties averaged 5000 ducks each yearly, or half a million of birds, and this without firing a shot, and adds, "during the last dozen years I have waged constant warfare against wildfowl, with all imaginable contrivances in the way of yachts, punts, and guns, in various parts of the world, as well as at home, at a cost of—I should be afraid to say how much time and money—yet I can account for but six or seven thousand ducks. Now, in *one* winter alone, it was in our grandfathers' days a usual thing for a decoyman to catch from five to ten thousand birds, at an annual outlay of perhaps 50*l.* spent in keeping up a pond and its netting, its pipes, and its reed screens." The price realised by the fowl at the commencement of the present century seems trivial enough as compared with that produced in the present day, but many decoys then made a return of from one to four hundred pounds per annum, perhaps even more, could the secrets of the decoymen be ascertained. In 1714 about 9*s.* 6*d.* per dozen birds seems to have been the price (it must be remembered that the smaller species of duck were counted as "half-birds," and went at twenty-four to the dozen); from thence the price appears gradually to have increased to 16*s.* per dozen in 1726. In 1765-66, 13,160 "whole-birds" (representing 18,000 fowl), captured at the Dowsley decoy, sold for 385*l.* 18*s.* 10*d.*

As might be expected of men exercising such an exceptional calling, the decoyman was clannish in the extreme; and Sir Ralph Gallwey gives some very interesting particulars of a family of typical decoymen named Skelton, who originally migrated from Firskney in Lincolnshire, where they had long followed the same occupation, into

Norfolk, in which county they remodelled most of the then existing decoys and constructed others. Descendants of the same family, having since removed to other counties, are some of them still celebrated for the skill with which they exercise the talent inherited from their forefathers. When "Old George Skelton" first came into Norfolk he found the decoy-pipes simply grouped around the margins of the "Broads," a plan which did not at all accord with his ideas of propriety, the great extent of water rendering it difficult if not impossible to have the fowl under what he considered proper control. He therefore selected a small piece of water of about two acres in extent on the banks of which to construct his decoy, much to the amusement of the local decoymen; but their derision was soon changed to amazement when in one week he captured 1100 teal in his "two-acre puddle" as they derisively termed it. The son of this man, also known as "Old George Skelton," was equally celebrated for his skill as a decoyman, and left his mark upon many of the Norfolk decoys. This man, says Sir Ralph Gallwey, is described as a "very peculiar man, short of stature, web-footed like a duck, very strongly built, particularly kind in disposition, perfectly indifferent to cold and hardship, well-informed, and unequalled in skill in the construction and management of decoys."

In the space at our disposal it would be impossible even to epitomise the full and elaborate instructions for erecting and working a decoy, given so clearly and precisely that the thirty-two plans and illustrations are scarcely necessary for their elucidation. But with such assistance there should be no difficulty in erecting the decoy, and by following the ample instructions experience would be gained in a season or two sufficient to enable almost any one to work the pipes with tolerable success; but the art of decoying is only to be acquired in perfection by careful and continued study of the habits of the frequenters of the decoy pond with practice added. We quite agree with Sir Ralph Gallwey that there cannot be a more interesting adjunct to an estate than a duck decoy, if even it be only worked on occasions to obtain a supply of fowl for the table of the proprietor and as acceptable presents to his friends: but should he be a naturalist and fond of the study of birds, a peep through the screen of his decoy at the fowl disporting themselves in a state of perfect unconsciousness under his very eye and almost within his grasp will go far towards repaying him the trifling outlay the decoy will entail. Nor need the fact of the decoy being worked preclude the proprietor from the occasional use of the gun: if not persistently disturbed the fowl will speedily return, and although it is undoubtedly to the advantage of the decoy to be perfectly secluded, a very successfully worked decoy is known to the writer in so exposed a situation that the fowl on the water may be seen from a public road which passes close by; it is astonishing how soon wildfowl become accustomed to sounds and sights which are not sudden or unexpected.

Sir Ralph Gallwey enumerates forty-four working decoys, and traces with more or less success the history of 149 others which have ceased to be used in England, and three active and nineteen disused decoys in Scotland; the sister island, so far as he can ascertain, never having possessed a decoy. Of this large number Lincolnshire possessed thirty-nine, only one of which is still worked; Essex thirty, three of which are still worked; Norfolk twenty-six, with five still worked; and Yorkshire fourteen, with two only still in use. The history of these decoys as given by Sir Ralph Gallwey will be found replete with antiquarian interest as well as with abundant matter for the consideration of the naturalist, and his chapter on the Lincolnshire Fens is especially interesting.

A short account is given of the decoys existing in Holland, from which country enormous numbers of fowl are exported annually, and which probably indicates the state of affairs which existed in this country in the palmy days of the duck decoy. A small woodcut on p. 200 shows a form of nesting basket used by the Dutch for their tame decoy ducks, and which would probably prove an excellent contrivance for inducing wild birds to nest in our own shrubberies and pleasure-grounds.

We cannot speak too highly of the plates and plans with which this handsome volume is illustrated, and we cordially recommend it to the perusal of all lovers of field-sports.

COMETARY AND PLANETARY ORBITS

Traité de la Détermination des Orbites des Comètes et des Planètes. Par le Chevalier Théodore d'Oppölzer, &c. Édition Française. Par Ernest Pasquier. (Paris: Gauthier-Villars, 1886.)

THIS is a translation from the second edition of the first volume of Prof. Oppölzer's laborious and truly classical work in German, on the theory and practical determination of the orbits of comets and planets. It has been made with the full assent and co-operation of the author, and with the assistance of Dr. Schram and others who greatly aided in the production of the original work. The volume comprises nearly 500 pages of text and 200 pages of tables, and is an excellent specimen of typography throughout. Oppölzer's first volume is divided into two parts, the first termed *preparatory*, the second treating of the determination of orbits in the various conic sections In the preparatory part we have chapters on the transformation of co-ordinates; on co-ordinates in their relation to the time and the relation between the position of the celestial body in its orbit and the corresponding epoch; likewise on the relation between a number of positions in the orbit. There is a chapter on aberration, and an important one on the theoretical determination of the formulæ of precession and nutation. The second part commences with the treatment of parabolic orbits, of which the numerous cometary discoveries of the present day necessitate so frequent application, and there are fully-worked numerical examples referring to the comets 1869 III. and 1881 III. This section is followed by a chapter, which will have much interest, on the determination of the orbit of a swarm of meteors by means of its radiant point, a problem which is reduced within a very small expenditure of time and calculation: a numerical example is worked out for one of Prof. Weiss's radiants. The next section treats of the calculation of the orbit where no assumption is made with respect to the excentricity: (1) from three observations only, as is more usually the case; (2) where four observations are introduced. The well-known general method of Gauss was published early in the present

century, and has been used in determining the orbits of a large number of the minor planets, and of the comets of short period. Oppölzer substitutes for it in his second edition one of his own, which, from extensive application he has found to be much superior to all other methods, both as regards the precision of the results and the rapidity with which the computations may be performed. In the case of the planet *Ceres* he obtained results on a first approximation more exact than those given by the method of Gauss after three approximations. Further, it is pointed out that, where four observations are employed, Gauss's method is not applicable, except when the excentricity is small. There is a chapter on the modifications of Oppölzer's method necessary in the determination of cometary orbits; also a numerical example for the orbit of the minor planet *Eudora*, and one for the first comet of 1866, or the comet of the November meteors, as well as a comparison of the new method with that of Gauss, by an example taken from the *Theoria motûs*. So far, three observations are employed. Similar examples follow for the case of four observations. A succeeding section deals with the calculation of circular orbits, and it is shown that an ephemeris deduced from a circular orbit, which admits of comparatively rapid and easy calculation, may be made of service in following for a time a newly-discovered minor planet. In an appendix are collected all the formulæ usually required in the first determinations of orbits, with reference to those parts of the volume where the analysis and other details are to be found—a *résumé* that possesses great value in so extensive a work. The tables which follow are on a greatly extended and refined system, more especially that for the calculation of the true anomaly in the parabola

The great work of Oppölzer, of which Prof. Pasquier has presented astronomers with so admirable a translation, is not one suited to a beginner; but the student with a certain knowledge of the differential and integral calculus, and of analytical mechanics, may initiate himself with its aid, as the translator remarks in his preface, "à l'un des problèmes les plus hardis que se soit posés l'intelligence humaine."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Silver-Blue Cloudlets again

FROM your last week's issue, p. 264, it would seem that the silver-blue clouds and cloudlets seen at midnight low down over the northern horizon both in this, and last, year's July are attracting much attention among your correspondents; but have not yet had the spectroscope directed to them.

Now there was a remarkable display of those bright blue clouds on the night of Tuesday, July 27, though with some variations on their exact mode of appearance in the *earlier* part of the month; but not necessarily removing them into a different category. The day had been cold but clear, especially in the northern direction, from which the wind was blowing, bar. = 29·60, night temp. = 48° F., depression of wet-bulb = 4°·0 F It was therefore just such a night as at this season of the year and in this high latitude is certain to show a coloured twilight over the sun's place beneath the northern horizon, if ordinary thick fogs, and low cloud-banks do not interfere.

On issuing, then, that night, close upon twelve o'clock, from the Observatory computing-room, upon the Calton Hill, I was surprised and even startled, not at seeing a low-down coloured twilight in the north, but at the excessive strength, and glittering brightness of its colours. You might indeed have, at first sight, imagined that some great city, spread abroad over the plains of Fife was in a fierce state of extensive conflagration, so burning red was the first and lowest stratum extending along nearly 20° of the horizon. But that awful kind of redness passed quickly into lemon-yellow clouds in the stratum next above the red; and then came the silver-blue cloudlets just above the lemon-yellow, and even brighter still; but with an innocence of colour and gentleness of beauty, which at once exorcised the horrid idea of malignant flames devouring the works of man; and showed it must be something very different.

But still what was it, that made that low level strip far away in the north, just then so brilliant in its light and intense in its colours,—that it, and it alone seemed for the time, to be illumining the otherwise pitchy darkness of night? At the same time a few stars were faintly visible; while a long streamer, of apparently white cirrus cloud, trailed over half the sky from west, to east-north-east, and passed across the Polar region at a considerable altitude, having the silver-blue cloudlets and their gorgeous red basement far below, but within, its wide-inclosing sweep.

On reaching home, I got a large spectroscope to bear on the brightest part of the low level streak of richly coloured light, its red, and yellow, and light blue, both collectively, and separately; but with no other decided effect than a short continuous spectrum in the green; which, as I have elsewhere long ago shown, is the spectrum of ordinary twilight always. For even though red and yellow be present to the eye at large, these colours rapidly fade out in any slit-formed spectrum, leaving the maximum of faint twilight placed by the prism as above described.

On this occasion, however, I did remark that that short continuous spectrum began in its citron, or commencing, region rather abruptly: in fact I even imagined a bright line there; and after several independent measures of spectrum-place, duly tested by reference both to a hydrogen tube, and the micrometer readings,—made out, that it was in the very position of the aurora line; or that, in fact, aurora was at that moment assisting, though to a very small extent, in that low streak of merely, but yet so intensely coloured, solar and Scottish, midsummer-midnight, northern, twilight.

Going next to the window, with a hand spectroscope, and examining the long ribbon of supposed white cirrus at some immense elevation,—it was startling as well as delightful to find it to consist of hardly anything but aurora; and to see aurora's chief line thin, sharp and positively brilliant along its whole extent; even appearing, if that could be, several times brighter, than its parent white streamer itself looked to the naked eye.

Nor did the identification, as aurora, of this fair white arc (transverse to a line leading to the magnetic pole), depend on the spectroscope alone: for, about 1 a.m., it began to form luminous, and rather yellowish, abutments to both its western and eastern terminations. Then its original singleness of curvature began to mould itself in the north-west into several curves of shorter radius; and after that, many thin arrows and shafts of light began to shoot out at right-angles from some parts of the great arc, and towards the zenith; and then, after a few minutes, died away. In fact it was to the eye a very fair auroral display, though the papers next morning said nothing about it.

But luminous manifestations were by no means the whole of what the aurora was doing; for presently I could conceal from myself no longer that the whole space below that long and high vaulting, white, upper arc was darkened, as compared against the sky elsewhere, with a brown-black hue; which moreover darkened still further and deepened in obscuration as it descended, until it suddenly ended sharply above, and quite close to, the silver-blue cloudlets of the low coloured twilight on the northern horizon.

Here then was a key at once to the apparently supernatural brilliance of the silver-blue cloudlets and the other colours below them; viz., all the broad expanse of ordinary further,

or outer, twilight, extending in reality to far beyond and above the place of the said cloudlets, was on this occasion painted, or blocked, out by dark dun colour. Nearly half the heavens were so obscured, and the earth below was as dark. No wonder then that the residual strip of untouched twilight shone so conspicuously in contrast.

But what is that darkness below an auroral arc?

It has been compared to the dark space under the negative pole of a highly rarefied gas-tube, when an electric spark is passed through it. And if we add in idea that it extends downwards to a certain angular distance from the sun, say 20°, and keeps to that,—the suggestion may explain why the silver blue cloudlets were seen higher over the northern horizon in the end of June and beginning of July, than at the end of the latter month; and also why they are never seen in the winter. But a still greater instrumental curiosity manifested itself in this, that the bright auroral citron-coloured line was also given in the spectroscope out of every part of that large expanse of auroral *shade*; and almost, though not quite, as well as from the bright track along its outer and upper edge; just as if, however dark to the unassisted eye, the black-brown space was yet somewhat luminiferous to the peculiar power of the prism.

On the next night after this interesting midnight experience, there was no aurora, and the twilight extended faintly to many degrees higher than the position of the blue clouds of the previous night, and in fact spread into and over the region which was before so decidedly "aurora blackened."

But the next night after that again, viz. two nights after the display, there was a wet drizzling mist which continued through the early hours until more than a quarter of an inch of rainfall had been gathered. Admirably confirming therefore the late Sir Robert Christison's often strongly expressed opinion that 48 hours after a great aurora, abundant rain is sure to follow,—an opinion too which I have only just heard was formed quite independently in Canada by my friend Mr. R. S. Haliburton, who is even now introducing it into his theory of "the aqueous origin of the aurora," so far as that can be carried; but without explaining either the citron line in the spectrum; or the effect on the magnetic needle. C. PIAZZI SMYTH

15, Royal Terrace, Edinburgh, July 31

The Bright Clouds

THE bright cirrus-like clouds are very common here this summer. I have seen them here on the nights of the 12th, 18th, 20th, and 24th of last month, and on the 1st inst., also at Gilsland on the 27th ult., in fact I do not know that in the last fortnight there has been a single night on which the northern sky has been quite free from lower clouds on which they have not appeared more or less; sometimes, however, they appear but for a short time, and in a very limited area of the sky. I have tried to keep a watch to see them in the day-time, but have not succeeded as yet; the nearest approach to success was on the 20th ult., when I saw them as early as 9.22 p.m., at which time they were visible over the greater part of the sky, but in the south-east were not strikingly bright.

There is one peculiarity with respect to them that I have not seen mentioned in NATURE, and that is their motion; on the above dates, except the 20th, I took notice of this, and in every instance the motion was from a northerly or easterly direction, whereas I have not noticed any ordinary cirrus moving from that quarter lately. Last night at from 10 to 10.15, when there were small patches of these curious clouds, there was also at the same time a great deal of ordinary cirrus moving from the west. This circumstance appears to indicate that there is quite a different current of wind in the upper atmosphere from that blowing at the lower elevation of ordinary cirrus.

I have no hesitation in saying that these extraordinary clouds do not shine with their own light, but with the direct light of the sun. T. W. BACKHOUSE

Sunderland, August 2

Aurora

THE following is a record of aurora observed on July 27 at Ramelton, co. Donegal:—

9.30 p.m.—From west to east there were occasional pencils of reddish lights shooting up, while from east to west there were continuous pencils of yellowish and reddish lights, with intermittent clouds and columns of reddish light, rising between the north-east and north-north-west. The pencils were very steady, but increasing and decreasing in length, at times assisted by the clouds of red forming a corona at the zenith round the star Capella (?), at such times as pencils shot up from the southward, on a rude irregular cross. The corona and cross appeared and disappeared quite rapidly. The clouds and columns of reddish light were succeeded by flashes and pencils of bright silver light, they being most frequent and brilliant between the north and west, the flashes being sometimes in long narrow wavy clouds that rapidly ascended, or narrow sheets that appeared and disappeared nearly instantaneously. They became more and more brilliant, especially to the north-north-west, till the display was greatest between 10.30 and 10.45.

10.45 p.m.—About this hour the continuous pencils of yellow and reddish lights between the east and west disappeared with the other lights, but about five minutes afterwards, to the northward, silver pencils and sheets appeared, veering from thence gradually towards the north-east and east. Some of the sheets hung at times in clouds that formed small arcs, that slowly rose obliquely, and moving eastward till about 11 o'clock, when all the lights disappeared, except that at long intervals faint pencils or flashes might shoot up on a small arc of silver clouds; but at 11.25 there was another brilliant display. First there appeared an arch of silver light, its centre being about north-north-west, then two arches that began sending up horns and pencils of light. The upper arch was a little below the North Star, while the lower one went through the Pointers of the Plough; these two arches were succeeded by one at 11.35. The crown of the arch was very unsteady, moving from north to north-north-west and back again, its shape and the accompanying horns and pencils continually changing, the most brilliant and highest pencils being those that shot up to the north-westward. This display continued more or less brilliant till 11.45, when clouds came up and prevented further observations; but at midnight the position of an arch was distinctly defined behind the clouds. At 1 a.m. the clouds had cleared away and no lights were visible. The night was not favourable for seeing an aurora, as it was very light and clear, yet at times the lights were very brilliant. Although the arches were of the same class of silver light as those seen from the North Atlantic or the Canadian Lakes, yet they were not steady like those, as they were continually shifting their positions or disappearing and reappearing. During the previous day there was a northerly wind with at times intensely cold squalls of misty rain.

G. H. KINAHAN

ABOUT 11.15 p.m. July 27, 1886, I observed an incipient stage of the aurora borealis, and about 0.10 a.m. of the 28th a considerable display of auroral colour commenced; but between 0.30 a.m. and 1 there was a vivid display of huge auroral sheets and columns; indeed, it did not require much to entitle the golden scene to the epithet—magnificent. There was a prismatic arc, not unlike a rainbow, which spanned from the north-west to the east, and measured about 70° from its centre to the horizon. All under this arc was a flood of white light, which the aurora did not in the least degree invade. From this arc developed a brilliant aurora borealis to a few degrees south of the zenith; and, with other constellations, Cygnus, Lyra, and the Northern Crown were overwhelmed in a golden flood. In this part of our northern latitude there are at present highly favourable conditions for phenomenal refraction of solar light. On the morning of the 27th and 28th the earth-shine on the moon was very bright, and I have no doubt but that these atmospheric conditions are also favourable to auroral displays. Every vestige of the aurora borealis disappeared about 2.30.

I do not think that an aurora as early as July is on record; in the Culloden meteorological records there is not one recorded so early as July from 1841 to 1880: indeed August is reckoned unusually early for an aurora borealis. I recollect a most magnificent one about the beginning of August in 1882, in the upper reaches of Lanarkshire; the huge vivid sheets and columns reached from the west all along the horizon to the east, and up the vault of heaven to the zenith, and with their fleet shifting flashes and bursts of prismatic coruscations, they lighted up the earth with ineffable glory.

Halos and Mock Suns

On Tuesday, July 20, about 5.15 p.m., I saw from this neighbourhood a most remarkable series of halos and parhelia, the general appearance of which is represented in the accompanying figure. (The parhelia at 120°, P^{iii} and P^{iv}, cannot be represented in the figure.)

As I happened to have a theodolite near at hand, I measured the altitudes and azimuths of the parhelia and contact arches, and also of two points on the larger halo, with the following result :—

	Azimuth by back angle	Altitude.	
Sun	320°	25°	
Parhelia	°	°	Angular distance from sun
P^{i}	347	25	27
P^{ii}	293	25	27
P^{iii}	80	25	120
P^{iv}	200	25	120
Contact-arch to inner halo	°		Radius of large halo from mean of two observations
Left extremity (A^{ii})	285	39	63° 30′
Right extremity (A^{i})	353	39	

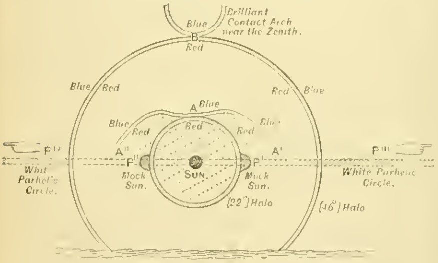
The positions of the two parhelia P^{iii} P^{iv} (or more properly speaking, *anthelia*) at 120° on either side of the sun, exactly accord with what is given in the text-books, but the solar longitude of the parhelia on the primary halo 27°, and the dimensions of the larger halo $63\frac{1}{2}°$, usually given as 46°, are greater than those usually recorded.

The following features were observed :—

(1) The parhelion, P^{ii} 27°, to the left of the sun, was very brightly visible before that on the right appeared at all.

(2) The parhelic circle appeared to encircle the entire sky, and to be everywhere of the same altitude—25°—as that of the sun.

(3) The contact arch, B, at the top of the larger halo, was remarkably brilliant, being red on the side adjacent to the sun,



and blue on that furthest from it, and appeared to be almost exactly at the zenith, thus supporting the somewhat rough measurements of the outer halo, which made it considerably larger than the traditional 46°.[1]

(4) The contact arches A^{i} A^{ii} were also very brilliant, and the space within them as well as that within the inner halo *h h* was much darker than that outside.

(5) The colours of the outer halo, H H, were similar to those of the inner halo, *h h*, viz. red inside and blue outside, but fainter.

(6) The parhelia attached to the inner circle P^{i} P^{ii} were similarly red inside and blue outside, while those at 120° were perfectly white.

The whole phenomenon lasted about twenty minutes, and was one of the most beautiful sights I ever saw. I was experimenting with a captive balloon at the time, or should have been able to make more detailed observations. I hear that on Monday night a deluge of rain of a tropical character fell at Dieppe. The cloud which caused these unusual optical phenomena appeared to be of the type termed by Poey globo-cirrus. I shall be glad to hear if any corroborative measurements were made by other observers.
E. Douglas Archibald

Tunbridge Wells, July

P.S. No parhelia were visible at the junction of the larger halo H H with the parhelic circle. Also there were no signs of the rare 90° radius halo. The radius of the inner halo was not measured, but as the lateral deviation of the parhelia P^{i} P^{ii} from the points in which it intersected the parhelic circle for a solar altitude of 25° should be about 2° 7′, this would make the radius of the inner halo 24° 53′ instead of 22° 30′ as is generally the case.

[1] Sun's altitude = 25°, radius of halo = $63\frac{1}{2}°$, which would make the lower extremity of the top contact-arch $88\frac{1}{2}°$ above horizon.

On Tuesday afternoon, 20th inst., while sketching near Cranbrook, in the Weald of Kent, I saw a magnificent example of mock suns and solar rainbow circles.

From an early part of the day the sky had been, I think, more splendid in its cloud arrangements of cirro-cumulus than I have ever seen in this or any other country, though I have always been a delighted student of these phenomena. From 10 a.m. to about 4 p.m. there was an incessant change of loveliness in the forms and positions of the clouds and the remarkable perspectives thereby produced, to the intense admiration of myself and wife. But about 4 o'clock one half of the heavens from the horizon to the zenith became nearly covered with a thin stratum of dark clouds, which resembled more than anything else innumerable long bundles of cotton fibre, placed in every possible direction. The other half of the sky was of the richest and most delicate ultramarine as a background, and the fleecy *mare's tail* and *flocks of sheep* cloudlets as the subjects. On the dark strata of clouds the mock suns made their appearance, the real sun shining through the clouds with great intensity.

The whole phenomenon did not fade out till nearly 6 o'clock. As I saw it for some time reflected in a large sheet of water, I had good opportunities of studying it.

The setting of the sun that night was the most gorgeous pageant—myriads of golden streamers, in groups, being sent up from purple and scarlet clouds. Robert H. F. Rippon

Jasper Road, Upper Norwood, July 28

N.B. The clouds in the vicinity of the sun were slightly opalescent.—R. H. F. R.

A Singular Case

On March 2 last a small fishing-boat engaged in trawling at about 20 kilometres from the coast, off Monte Argentaro (Tuscan Maremma), captured a specimen of the Mediterranean Red Mullet (*Mullus barbatus*) tightly incased in a large colony of *Pyrosoma atlanticum*. The head of the fish had reached the bottom of the social cylinder, which fitted it to a nicety. The *Pyrosoma* measures 0·112 millimetre in length and 0·032 millimetre at its greatest transverse diameter; the mullet is 0·152 millimetre long, so that only 0·040 millimetre of its tail projects beyond the tightly fitting *Pyrosoma!* The fish was taken *alive*, but how it could have lived in such conditions or how it got into its tight jacket is to me most enigmatical. Even admitting a certain amount of elasticity in the tight-fitting tube in which its head, body, and fins are incased, its movements could only have been very limited, and a very incomplete respiration and perhaps nutrition might have come to it through the orifices of the zooids.

Young fish, especially Scomberoids, are often found under the shelter of Medusæ and *Physalia*—the case of *Fierasfer* getting into the visceral cavity of *Holothuria* is well known; but it is the first time I have seen or heard of so singular a case of imprisonment as the one related above, and I therefore thought it worthy of the attention of the readers of Nature. The specimen is preserved in alcohol in the rich ichthyological series of the collection of Italian Vertebrata in the Florence Royal Zoological Museum. Henry H. Giglioli

Florence, July 29

The Weather at Caracas

The following notes on the weather at Caracas during the remarkable storm from May 11 to 15 may not be void of interest :—

We had a rather low barometer on May 8 (10 a.m., 682·93 mm.; 4 p.m., 681·99 mm.), but then it rose gradually till May 18 (685·42 and 683·17 mm. respectively). There had been no rain in the first twelve days of the month, but from

May 13 to 16 there fell 106 mm. rain, about *one-ninth* of our total yearly quantity; on the 13th, 26 mm.; 14th, 27·6; 15th, 22·4; 16th, 30. These heavy rains were undoubtedly due to the northern storm, although they came two days later.

Caracas, June 29 A. ERNST

The Indivisibility of Certain Whole Numbers

ANOTHER exception has been found to Fermat's assertion regarding the indivisibility of whole numbers of the form $2^{2^m}+1$ (see several notices in NATURE, vols. xviii. and xix.). The matter now stands as follows:—

$2^{2^5}+1$	divisible by	$5\cdot2^7+1$	(Euler)
$2^{2^6}+1$	,,	$1071\cdot2^8+1$	(Landry)
$2^{2^{12}}+1$	,,	$7\cdot2^{14}+1$	(Pervouchine)
$2^{2^{23}}+1$	,,	$5\cdot2^{25}+1$	(Pervouchine)
$2^{2^{36}}+1$	,,	$5\cdot2^{39}+1$	(Seelhoff).

M.

A Quadruped Duck

IT may interest some readers of NATURE to hear that there is at present living in Bardsea a duck which has four feet. The two abnormal feet, which are webbed like the others, and of the same shape and size, spring from one leg, which is about the same length as the normal legs, but rather thicker. This leg grows from a point just beneath the tail. Its bone does not seem to be directly connected with the other bones of the bird, as it can be freely moved in any direction. This duck is more than a month old, and is healthy. EDWARD GEOGHEGAN

Bardsea, August 3

PHYSIOLOGICAL SELECTION: AN ADDITIONAL SUGGESTION ON THE ORIGIN OF SPECIES[1]

I.

THERE are three cardinal difficulties in the way of natural selection, considered as a theory of the origin of species.

(1) The difference between species and varieties in respect of mutual fertility. Many of our domesticated varieties differ from one another to an extent greater than that which distinguishes many natural species: yet they continue perfectly fertile *inter se*, while the natural species are nearly always more or less sterile. The difficulty is not met by pointing to the fact that sterility between natural species is neither absolutely constant nor constantly absolute; for the question still remains, Why are the modifications of organic types supposed to have been produced by natural selection, so generally attended with some more or less pronounced degree of mutual sterility, when even greater modifications of such types produced by artificial selection so generally continue mutually fertile? That this question does not admit of any answer by the theory of natural selection Mr. Darwin himself acknowledges, and therefore suggests a wholly independent hypothesis by which to explain the fact. This hypothesis is, that varieties occurring under nature "will have been exposed during long periods of time to more uniform conditions than have domesticated varieties, and this may well make a wide difference in the result." Now, whatever we may think of this hypothesis, it is certainly quite distinct from the theory of natural selection; and, therefore, any one who adopts the supplementary hypothesis is, so far, confessing the inadequacy of that theory, considered as a theory of the origin of species. For my own part, I deem the hypothesis wholly insufficient to meet the facts. When we remember the incalculable number of species, living and extinct, we immediately feel the necessity for some much more general explanation of their existence than is furnished by supposing that their mutual sterility, which constitutes their most general or constant distinction as species, was in every case due to some incidental effect produced on the generative system by uniform conditions of life. To say nothing of the antecedent improbability that in all these millions and millions of cases the reproductive system should happen to have been affected in this peculiar way by the merely negative condition of uniformity, there remains what seems to me the overwhelming consideration that, at the time when a variety is first forming, the condition of prolonged exposure must necessarily be absent as regards that variety: yet this is just the time when we must suppose that the infertility with its parent form arose. Because, if not, the incipient variety would have been reabsorbed into its parent form by intercrossing.

(2) For the swamping effects of free intercrossing upon an individual variation constitutes the next, and perhaps the most formidable, difficulty with which the theory of natural selection is beset. The only answer which Mr. Darwin has to make in this case is that a number of individuals inhabiting the same area may vary in the same way at the same time. Of course, if this assumption were granted, there would be an end of the present difficulty; for if a sufficient number of individuals were thus similarly and simultaneously modified, there need no longer be any danger of the variety being swamped by intercrossing. But the force of the difficulty consists in the very fact of this assumption being required to meet it. The theory of natural selection trusts to the chapter of accidents in the matter of variation; and in this chapter we read of no reasons why the same beneficial variation should arise in a number of individuals simultaneously. Moreover, if it does so, the fact of its doing so cannot be attributed to natural selection, which thus again fails as a theory of the origin of species. Lastly, as will immediately be shown, a very large proportion, if not the majority, of features which serve to distinguish species from species, are features presenting no utilitarian significance; and, therefore, even if it be conceded that they each arose in a number of individuals simultaneously, their reabsorption by intercrossing could not have been in any degree hindered by natural selection.

(3) The difficulty just alluded to of the inutility to species of so large a proportion of specific distinctions, is one which Mr. Darwin frankly acknowledges in the later editions of his works. In other words, he allows that a large proportion of these distinctions resemble the more general distinction of sterility in not admitting of any explanation by the theory of natural selection. They consist of small and trivial differences of form and colour, or of meaningless details of structure, which, being of no service to the plants or animals presenting them, cannot have arisen through the agency of natural selection. If it be suggested that all such distinctions are of disguised utility, the answer is that to offer this suggestion is to reason in a circle. For the only evidence we have of natural selection as an operating cause in any case is derived from the utility of the observed results: therefore, in cases where utility is apparently absent, we may not assume that it must be present only because, if it were not present, the results must be due to some cause other than natural selection. Observe, the case would be different if the great majority of specific distinctions—like the great majority of higher distinctions—were of obvious utilitarian significance; for in this case we might reasonably set down the exceptions as proof of the rule, or hold that they appear to be exceptions only on account of our ignorance. But it is certainly too large a demand on our faith in natural selection to appeal to the argument from ignorance when the facts require that the appeal should be made over so very large a proportion of instances. But it is needless further to insist upon this

[1] Abstract of a Paper read before the Linnean Society on May 6, by George J. Romanes, M.A., LL.D., F.R.S. &c.

point, since, as I have already observed, its force has been fully recognised by Mr. Darwin and his followers. Here again, therefore, the theory of natural selection fails as a theory of the origin of species.[1]

In view of these three grave disabilities under which the theory of natural selection lies, I feel entitled to affirm that the theory has been misnamed. Natural selection is not, properly speaking, a theory of the origin of *species*: it is a theory of the origin—or rather of the cumulative development—of *adaptations*, whether these be morphological, physiological, or psychological; and whether they occur in species only, or likewise in genera, families, orders, or classes. These two things are very far from being the same; for, on the one hand, in an enormously preponderating number of instances, adaptive structures are common to numerous species, while, on the other hand, the features which serve to distinguish species from species are, as we have just seen, by no means invariably—or even generally—of any adaptive character. If once it is thus clearly perceived that the theory of natural selection is not a theory of the origin of species, but a theory of the development of adaptive structures—whether these happen to be distinctive of species or of higher taxonomical divisions—if once this is clearly perceived, the theory is released from all the difficulties which we have been considering. For these difficulties have beset the theory only because it has been made to pose as a theory of the origin of species, whereas in point of fact it is nothing of the kind. In so far as natural selection has had anything to do with the genesis of species, its operation has been, so to speak, incidental: it has only helped in the work of originating species in so far as some among the adaptive variations which it has preserved happen to have constituted differences of merely specific value. Many other such differences there are with which natural selection has had nothing to do—particularly the most universal of all such differences, or that of mutual sterility—while, on the other hand, by far the larger number of adaptations which have been the work of natural selection are now the common property of genera, families, orders, or classes. Let it, therefore, be clearly understood that it is the office of natural selection to evolve adaptations: not necessarily, or even generally, to originate species.

Let it also be clearly understood that in thus seeking to place the theory of natural selection on its true logical footing, I am in no wise detracting from the importance of that theory. On the contrary, I am but seeking to release the theory from the difficulties with which it has been hitherto illegitimately surrounded.

Enough has now been said to justify the view that there must be some cause or causes other than natural selection operating in the evolution of species. And this is no more than Mr. Darwin himself has expressly and repeatedly stated to have been his own view of the matter; nor am I aware that any of his followers have thought otherwise. Hitherto the only additional causes of any importance that have been assigned are use and disuse, sexual selection, correlated variability, and yet another principle which I believe to have been of much more importance than any of these. Yet it has attracted so little attention as scarcely ever to be noticed by writers on evolution, and never even to have received a name. For the sake of convenience, therefore, I will call this principle the Prevention of Intercrossing with Parent Forms, or the Evolution of Species by Independent Variation.

First let us consider how enormous must be the number of variations presented by every generation of every species. According to the Darwinian theory it is for the most part only those variations which happen to have been useful that have been preserved: yet, even as thus limited, the principle of variability is held able to furnish sufficient material out of which to construct the whole adaptive morphology of nature. How immense, therefore, must be the number of unuseful variations! Yet these are all for the most part still-born, or allowed to die out immediately by intercrossing. Should such intercrossing be prevented, however, there is no reason why unuseful variations should not be perpetuated by heredity quite as well as useful ones when under the nursing influence of natural selection—as, indeed, we see to be the case in our domesticated productions. Consequently, if from any reason a section of a species is prevented from intercrossing with the rest of its species, we might expect that new varieties (for the most part of a trivial and unuseful kind) should arise within that section, and that in time these varieties should pass into new species. And this is exactly what we do find. Oceanic islands, for example, are well known to be extraordinarily rich in peculiar species; and this can best be explained by considering that a complete separation of the fauna and flora of such an island permits them to develop independent histories of their own, without interference by intercrossing with their originally parent forms. We see the same principle exemplified by the influence of geographical barriers of any kind, and also by the consequences of migration. When a species begins to disperse in different directions from its original home, those members of it which constitute the vanguard of each advancing army are much more likely to perpetuate any individual variations that may arise among them than are the members which still occupy the original home. For not only is the population much less dense on the outskirts of the area occupied by the advanced guard; but beyond these outskirts there lies a wholly unoccupied territory, upon which the new variety may gain a footing during the progress of its further migration. Thus, instead of being met on all sides by the swamping effects of intercrossing with its parent form, the new variety is now free to perpetuate itself with comparatively little risk of any such immediate extinction. And, in the result, wherever we meet with a chain of nearly allied specific forms so distributed as to be suggestive of migration with continuous modification, the points of specific difference are trivial or non-utilitarian in character. Clearly this general fact is in itself enough to prove that, given an absence of overwhelming intercrossing, independent variability may be trusted to evolve new species. The evidence which I have collected, and am collecting, of the general fact in question, must be left to constitute the subject of a future paper.[1]

Were it not for the very general occurrence of some degree of sterility between even closely allied species, and were it not also for the fact that closely allied species are not always separated from one another by geographical barriers, one might reasonably be disposed to attribute all cases of species-formation by independent variability to the prevention of intercrossing by geographical barriers, or by migration. But it is evident that these two facts can no more be explained by the influence of geographical barriers or by migration than they can by the influence of natural selection. The object of the present paper is to suggest an additional factor in the formation of specific types by independent variability, and one which appears to me fully competent to explain both the general facts just mentioned.

[1] Of the three cardinal objections to the theory of natural selection thus briefly stated, Mr. Darwin himself appears to have attributed most importance to the first, seeing that its consideration occupies so large a portion of his writings. The objection from intercrossing, on the other hand (which was first rendered with much force and clearness by the late Prof. Fleeming Jenkin of Edinburgh, in an anonymous article, *North British Review*, 1867), is the only difficulty in the way of his theory which Mr. Darwin can fairly be said not to have sufficiently treated. The objection from inutility was first prominently raised by Bronn. It was afterwards developed by Nägeli, Broca, Mivart, and many other writers.

[1] So far as I am aware, the first writer who insisted on the importance of the prevention of intercrossing in the evolution of species, both by isolation and migration, was Moritz Wagner. Since then Wallace, Weismann, and others have recognised this factor. The most recent contribution to the subject is an admirable collection of facts published by Mr. Charles Dixon in a work entitled, "Evolution without Natural Selection," which was recently reviewed in these columns But I cannot find that any of these writers allude to the principle which it is the object of the present paper to enunciate, and which is explained in the succeeding paragraphs.

Of all parts of those variable objects which we call organisms, the most variable is the reproductive system; and the variations may be either in the direction of increased or of diminished fertility. Having, regard, therefore, to all the delicate, complex, and for the most part hidden conditions which determine this double kind of variation within the limits of the reproductive system, there can be no difficulty in granting that variations in the way of greater or less sterility must frequently occur both in plants and animals in a state of nature. Probably, indeed, if we had the means of observing this point, we should find that there is no one variation more common. But, of course, whenever it arises—whether as a result of changed conditions of life, or, as we say, spontaneously—it immediately becomes extinguished, seeing that the individuals which it affects are less able (if able at all) to propagate the variation. But now, if the variation should be such that, while showing some degree of sterility with the parent form, it continues to be perfectly fertile within the limits of the varietal form, in this case the variation would neither be swamped by intercrossing, nor would it die out on account of sterility. On the contrary, this particular variation would be perpetuated with more certainty than any other variation, whether useful or unuseful. An illustration will serve to render this more clear.

Suppose the variation in the reproductive system is such that the season of flowering or of pairing becomes either advanced or retarded. Whether this variation be, as we say, spontaneous, or due to any change of food, climate, habitat, &c., does not signify. The only point we need here attend to is that some individuals, living on the same geographical area as the rest of their species, have varied in their reproductive systems so that they are perfectly fertile *inter se*, while absolutely sterile with all other members of their species. By inheritance there would thus arise a variety living on the same geographical area as its parent form, and yet prevented from intercrossing with that form by a barrier quite as effectual as a thousand miles of ocean: the only difference is that the barrier, instead of being geographical, is physiological

From this illustration I hope it will be obvious that wherever any variation in the highly variable reproductive system occurs, tending to sterility with the parent form without impairing fertility with the varietal form—no matter whether this be due, as here supposed, to a slight change in the season of reproductive activity, or to any other cause—there the physiological barrier in question must interpose, with the result of dividing the species into two parts. And it will be further evident that when such a division is effected, the same conditions are furnished to the origination of new species as are furnished to any part of a species when separated from the rest by geographical barriers or by migration. For now the two sections of the species, even though they be living on the same area, are free to develop distinct histories without mutual intercrossing, or, as I have phrased it, by independent variation.

To state this suggestion in another form. It enables us to regard many, if not most, natural species as the records of variation in the reproductive systems of ancestors. When accidental variations of a non-useful kind occur in any of the other systems or parts of organisms, they are, as a rule, immediately extinguished by intercrossing. But whenever they happen to arise in the reproductive system in the way here suggested, they must inevitably tend to be preserved as new natural varieties, or incipient species. At first the difference would only be in respect of the reproductive system; but eventually, on account of independent variation, other differences would supervene, and the new variety would take rank as a true species.

The principle thus briefly sketched in some respects resembles, and in other respects differs from, the principle of natural selection, or survival of the fittest, as I will show later on. For the sake of convenience, therefore, and in order to preserve analogies with already existing terms, I will call this principle Physiological Selection, or Segregation of the Fit.

Before proceeding to state the evidence of the particular kind of variation on which this principle depends, let it be noted that we are not concerned either with its causes or its degrees. Not with its causes, because in this respect the theory of physiological selection is in just the same position as that of natural selection: it is enough for both that the needful variations are provided, without its being incumbent on either to explain the causes which underlie them. Neither are we concerned with the degrees of sterility which the variation in question may in any particular case supply. For whether the degree of sterility with the parent form be originally great or small, the result of it will in the long run be the same: the only difference will be that in the latter case a greater number of generations would be required in order to separate the varietal from the parent form.

(*To be continued.*)

TROPICAL FRUITS [1]

THE present Colonial and Indian Exhibition has developed interest in tropical fruits to an extent not previously known in England; and whatever may be the individual merits of many of the fruits displayed in the colonial market attached to the Exhibition, no one can deny that they afford proof of numerous undeveloped resources of our colonial possessions in a direction hitherto very much undervalued or entirely overlooked. Sir Joseph Hooker, in one of his journals, has remarked that "most tropical fruits are edible, but few are worth eating." But, after all, the merits of many fruits like those of certain wines are only properly appreciated under a concourse of local circumstances which materially affect our verdict. In the tropics the desire for refreshment and for something cooling and piquant is met by a fruit which, at the moment, completely answers the purpose. Transferred to a cooler climate, the same fruit may be entirely out of place, and indeed may be condemned as valueless. As a case in point, the water of a young cocoa-nut, when clear and fresh, taken from the fruit after a long ride in the sun, is most refreshing and wholesome. The same thing tried in the climate of England, and with fruit imported from the tropics, would be nauseous and wholly unpalatable. Similar remarks would apply to the fruit of the mangosteen, the durian, and many others where it is necessary that the fruit should be eaten when just ripe, and where a long journey affects the quality and impairs the delicacy—both being of an evanescent character.

Again, it is necessary to bear in mind how to use certain tropical fruits in order to appreciate them to the best advantage. Owing to the loose manner in which tropical fruits are termed, apples, plums, pears, peaches, &c., when they are neither botanically nor intrinsically anything of the sort, there has arisen considerable confusion respecting them. Again, many tropical fruits are suitable only for salads or curries, and should not appear at the dessert table at all. Others are better when preserved or cooked, and they are then both wholesome and well adapted to the wants of the country. There is no good pear (*Pyrus communis*, L.), as known in England, grown in the tropics, yet we have the name applied to the Alligator or Avocado pear (*Persea gratissima*, Gart), the anchovy pear (*Grias cauliflora*, L.), the prickly pear (*Opuntia ficus-indica*, Webb), and the wooden pear of Australia (*Xylomelum pyriforme*, Knight). Again, the English apple, although grown in the hills in the tropics, is practically of little value, but the name is as loosely applied as in the case of the pear, and hence fruits as widely apart as the poles in their botanical classi-

[1] Lecture given in the Conference Hall, Colonial Exhibition. Revised by the Author.

fication are grouped together under the general term of apple. To select a few out of many such names, we have the sugar or custard apple (*Anona reticulata*, L.), the Kei apple (*Aberia caffra*, H. and S.), the Mammee apple (*Mammea americana*, L.), the star apple (*Chrysophyllum Cainito*, L.), the rose apple (*Eugenia Jambos*, L.), and the golden apple (*Spondias lutea*, L.). In plums there are the Caffre plum (*Harpephyllum caffrum*, Bernh.), the coco plum (*Chrysobalanus icaco*, L.), the hog plum (*Spondias mangifera*, Pers.), the Chinese date plum (*Diospyros kaki*, Lin. fil.), the blood plum (*Hæmatostaphis Barteri*, H. K.), and the gray plum of Sierra Leone (*Parinarium excelsum*, Sabine); and so with the gooseberry, essentially a cold temperate fruit, English colonists have applied the name to such widely-diverging fruits as those of *Physalis Peruviana*, L. (Cape gooseberry), *Peirescia aculeata*, Mill (Barbados gooseberry), and *Cicca disticha*, L. (Otaheite gooseberry).

The so-called Nuts of the Tropics are in a worse state of confusion as regards the common names, and hence it by no means follows that what are imported as nuts belong at all to that category of fruits. The most familiar of tropical nuts is the cocoa-nut (*Cocos nucifera*, L.), a true nut; but the Para or Brazil nut (*Bertholetia excelsa*, H. B.) is simply the seed, not nut, which is inclosed in a large globular fruit, almost as large as a 36-pound cannon-ball; exactly the same occurs in the case of the Sapucajo nut (*Lecythis Zabucajo*, Aub.) as well as in the best of these so-called tropical nuts, viz. the souari or butter-nut of British Guiana (*Caryocar nuciferum*, L.). The cashew nut (*Anacardium occidentale*, L.) is a fruit borne upon a swollen pear-like peduncle, and presents one of the most remarkable instances of growth met in the tropics. The fruit when roasted is esteemed at dessert, and passes in India under the name of "promotion nut." The Jamaica walnut (*Aleurites moluccana*, Willd) is the seed of an Euphorbiad, as also the cob-nut (*Omphalea triandra*, L.).

From the above remarks it will be noticed from what various sources, and from what a diversified range of plants tropical fruits are derived. Also that little dependence can be placed on the common English names applied to these fruits. Where obtainable little objection can, however, be made against adopting the native or aboriginal names of tropical fruits, as in many cases they are sufficiently distinct, and at the same time are associated with circumstances of a local character, which render the name of permanent value. On this account a native or aboriginal name is quite as good, locally, as the scientific name; but of course it loses its value outside its own country. We have incorporated the aboriginal name in the case of the pine-apple (*Ananas sativa*, L.), and many instances of a similar character are found in the nomenclature of Indian and Chinese fruits.

Although not strictly speaking a tropical fruit, the orange is found in both the eastern and western tropics, and it is the best known of any foreign fruit. Large increase has occurred in the importation of this fruit to England within the last few years, and the present consumption is at the rate of $4\frac{1}{2}$ million bushels per annum, or equal to a consumption of sixteen oranges per head of population. Of fruits belonging to the same natural order as the orange there are the lemon (*Citrus medica*, var. *Limonum*, Brand), not largely grown in the tropics; the shaddock, or pumelo (*Citrus decumana*, L.), a fruit often 24 inches in circumference; the citron (*Citrus medica*, Riss.), chiefly used for "candied peel;" and the lime (*Citrus medica*, var. *acida*, Brand), which is chiefly known as the West India lime, and largely grown for making lime juice, raw and concentrated, for the manufacture of citric acid. This West Indian lime should take the entire place of the lemon in the English market, and when used in cooking gives a most piquant and refreshing flavour, not obtainable from any other source.

The banana generally found in the English market is the dwarf Chinese fruit (*Musa Cavendishii*, Paxt.). This is smaller and not so good as the true banana (*Musa sapientum*, L.), of which there are numerous varieties. The banana chiefly grown for export purposes in the West Indies is called the Martinique banana, a large yellow fruit about 6 to 8 inches long. The Cuban banana is a red-skinned variety, much coarser than the Martinique fruit, and only eaten when very "full," or in the ripe state of an English medlar. A variety of the banana with short thick fruits of very choice quality is called the fig banana, and this is esteemed as the best of the family, and consumed locally. The plantain (*Musa paradisiaca*, L.), is practically the tropical potato, and is used roasted, boiled, or fried, exactly as we use potatoes in England. At the present time the consumption of bananas in the United Kingdom is comparatively small. Some of the steamers trading with the West Indies are, however, being fitted with refrigerating chambers for carrying tropical fruit, and the banana should soon become as plentiful and as cheap as the orange. It has the merit of being wholesome and nutritious, and is suitable for invalids and young children as well as for dessert purposes.

The pine-apple we have already noticed. This is a deliciously refreshing fruit with healthful juices, and the demand for it is increasing daily. Hitherto, foreign pine-apples, which are gradually driving the home-grown fruit out of the market, are obtained in large quantities from the Azores. The further supply will no doubt come from the West Indies, where pine-apples can be grown in the open air as readily and as cheaply as the English farmer can grow beets or turnips. Unfortunately the choice varieties of pine-apples possess, as the growers say, "bad keeping" qualities; but with increased facilities for packing and stowing the fruit, there should be no difficulties of an insurmountable character in the way of bringing over pine-apples from the West Indies in excellent condition. At the colonial market attached to the Colonial and Indian Exhibition pine-apples from Antigua are sold at sixpence each, and we find from the Blue Book Report that the Bahamas export annually, either in a fresh or canned state, pine-apples to the value of 50,000*l*. annually. The mango (*Mangifera indica*, L.) is the apple of the tropics, and the mango tree is grown and occupies orchards as do apple-trees in England. Although an East Indian tree, it has become thoroughly naturalised in the west, where it spreads by self-sown seedlings over all waste places. Its introduction into Jamaica is thus described by Lunan ("Hortus Jamaicensis," 1814, p. 486):—"This beautiful tree was one of those brought to this island in June 1782, and taken in a French ship, bound for Hispaniola, by Capt. Marshall, of His Majesty's ship *Flora*, one of Lord Rodney's squadron. Capt. Rodney, with the approbation of Lord Rodney, deposited the mango plants and a great many others taken in the same vessel in Mr. East's garden (at Gordon Town), where they were cultivated with great assiduity and success, and have now become one of the commonest fruit-trees in Jamaica, in a great number of its varieties." As the mango ripens in July and August, and would come into the English market at a time when our own fruits are plentiful, it is possible it will not be greatly in demand. The best varieties are the Bombay sorts, while in Jamaica one of the plants deposited by Lord Rodney and having a number only, is is still known there and highly esteemed as "No. 11."

The passion fruits, of which there are several species, are highly prized. Of these there are the granadilla (*Passiflora quadrangularis*, L.), the pomme d'or, or water lemon (*P. laurifolia*, L.), the sweet cup (*P. edulis*, L.), and the calabash sweet-cup (*P. maliformis*, L.).

From the East Indies few if any fruits can be imported to England with success. In fact Ceylon and India have very few fruits which they can easily spare capable of bearing a long sea voyage, and the choice

fruits of Singapore and the Malay States are still further removed by time and distance.

At the Exhibition there is shown, from India, a small dried apricot (*Prunus armeniaca*, L.), an important article of food in the Punjaub Himalayas and in the North-west Provinces, which deserves attention as a probable source of an import trade for the English market. This fruit is known in India as the mish-mush, or "Moon of the Faithful." Dr. Watt remarks that it is largely eaten by all classes, fresh or dried, but chiefly fresh, and sometimes in preserve by Europeans. Sometimes the apricots are pressed together, and rolled out into thin sheets or "moons," 2 or 3 feet in diameter, like a blacksmith's apron. From Afghanistan large quantities of the dried fruit are imported into India, and distributed by trade far into the plains of Bengal.

Kew D. MORRIS

MICROSCOPIC ORGANISMS IN AIR AND WATER[1]

THIS Report is part of the "Annuaire de l'Observatoire de Montsouris" for the year 1885, and is worthy of careful study at the present time, when bacteriology is recognised as a special and important department of science. These investigations have been carried on at Montsouris since the year 1875, and through them Dr. Miquel has been enabled to throw much light on the meteorological aspect of the subject—an aspect that has received but little attention from investigators, as compared with the pathological. Every one will acknowledge that in entering upon a new field in scientific investigation it is extremely important that the line of research should proceed upon as broad a basis as possible, and that the work of experimentation and observation should not be confined to one aspect of the new study, however important it may be. Fallacies are sure to arise when any department of science is too narrowly specialised, from want of that more general knowledge which would prevent the adoption of erroneous views. This is especially liable to be the case in bacteriology, in which the objects of study are so minute and yet so widely distributed in nature. Dr. Miquel's researches—important as they are in themselves—are doubly welcome at the present time, as tending to popularise a field in which workers are urgently needed, as well as contributing largely to our knowledge. The example of Paris—the only city in which systematic investigations of the sort are now undertaken—should stimulate other towns which possess properly equipped meteorological laboratories, to conduct observations on the bacterial organisms contained in air, rain, and soil. The results obtained at Montsouris could then be confirmed or confuted by the results obtained at other laboratories under widely different climatic and meteorological conditions, and the enunciation of general laws and principles would in time become possible. We shall endeavour to place before our readers in this article some of the more important results and deductions made from them by Dr. Miquel, from the observations at Montsouris; but it should be distinctly recognised that any conclusions arrived at by Dr. Miquel are applicable only to Paris and its neighbourhood, and cannot at present be accepted as true for other places where the climatic conditions are different.

Tables are given in the Report, showing for each week of the years 1883-84 (*a*) the average number of bacterial micro-organisms present in a cubic metre of air, (*b*) the average barometrical pressure, (*c*) the average temperature of the air, (*d*) the average state of humidity of the air [percentage of saturation], (*e*) the amount of rainfall, (*f*) the electrical state of the air, (*g*) the direction and average velocity of the wind, (*h*) the average amount of ozone present in the air. From the observations recorded in these tables, Dr. Miquel has arrived at the following conclusions:—(1) An increase in the number of bacterial organisms contained in a cubic metre of air generally takes place when the barometrical pressure is high: this rule is not absolute, but the exceptions are rare. (2) Temperature does not cause such sudden increments; very often, it is true, a large increase in the number of microbes present in the air takes place in summer, but it is important to note that a sustained high temperature causes a manifest lessening in their number. The thermometer is capable of explaining certain seasonal variations, but not the weekly variations. (3) The maximum number of bacterial organisms present in the air corresponds almost always with a low hygrometric condition of the atmosphere; this is explained by the fact that the degree of humidity is always very high during rain, and when the superficial layers of the soil are soaked in water, periods during which the air is always very poor in bacteria. (4) It would appear *a priori* that the number of bacteria should increase with the strength of the wind, but observation negatives this assumption. A maximum number of microbes is found frequently during periods of calm—when the velocity of the wind is only 5-10 kilometres per hour—and minima have been observed during periods when the velocity of the wind was more than 30 kilometres per hour. (5) The direction of the wind exercises a considerable influence at Montsouris. The greatest number of maxima are noted when the wind is N.E., and the greatest number of minima when the wind is S.W. (6) When the amount of ozone in the air is large, the number of microbes present is small. The north winds blow over from Paris and contain but little ozone. They are rich in microbes. The presence of ozone in the air appears to have the power of destroying bacterial organisms, and, on the contrary, absence of ozone and humidity of the air—unless rain is falling—allow of an increase taking place in their number.

From observations at Montsouris, extending over a period of five years—1880-84—the average number of bacterial organisms in a cubic metre of air is stated to be: in winter 260, in spring 495, in summer 650, in autumn 380; the mean annual number being 445. In February the air is poorest in bacteria [the average of these five years is 165]. Towards the middle of summer the maxima present themselves [July 700].

Observations have also been conducted for a period of four years—1881-84—on the state of the air, as regards bacteria, in the centre of Paris. These observations were made on the air of the Rue de Rivoli, and afford a marked contrast in the number of micro-organisms to the far purer air of Montsouris, a suburb of Paris, and where, it is important to remember, the Observatory is situated in the centre of a park. The average of these four years' observations shows that the air of the Rue de Rivoli contains 3480 bacteria per cubic metre. The seasonal fluctuations are nearly the same as at Montsouris, the minimum being in February (1700) and the maximum in July (5010). The average number of bacteria present in a cubic metre of air, for the year 1881, was 6295, whilst the average number for 1884 was only 1830. This enormous decrease—which is observed in the intervening years to a slighter extent—is attributed by Dr. Miquel to the better drainage and scavenging of the city, and to the better cleansing of the gutters and watering of the streets in dry dusty weather, in 1884 than in 1881. The death-rate from zymotic diseases—in which are included typhoid fever, small-pox, measles, scarlatina, whooping-cough, diphtheria, dysentery, erysipelas, puerperal fevers, and choleraic diarrhœa of infants—has also fallen very considerably—27 per cent., if increase of population is taken into account—during this period. The death-rate of

[1] "Septième Mémoire sur les Organismes Microscopiques de l'Air et des Eaux," par M. le Dr. Miquel, Chef du Service Micrographique à l'Observatoire de Montsouris.

phthisis or consumptive diseases has, however, increased during the same period, although those of acute bronchitis and pneumonia have decreased. Acute pneumonia is now considered by many to be propagated by infection from specific organisms occasionally present in the air. The curves for the year 1883-84, representing the average weekly number of bacteria present in a cubic metre of the air of the Rue de Rivoli, A, and the weekly deaths from zymotic disease, B, are shown in Fig. 1. The curves are seen to present somewhat similar fluctuations except at the end of July and the first half of August, when the number of bacteria suddenly decrease—owing to the hot weather and sustained high temperature—whilst the deaths from zymotic disease undergo a large increase, owing to excessive mortality from infantile diarrhœa. The variations in the number of bacteria from week to week will be seen to be very much larger and more sudden than the variations in the zymotic death-rate. Very little can be deduced from comparisons extending over one year only, and although we are far from asserting that there can be no mutual relation between the number of micro-organisms present in the air, and the greater or less prevalence of epidemic disease among the community who breathe such air, still it is unsafe to found any arguments on such obviously inadequate data. It is only just to Dr. Miquel to say here that he recognises these difficulties, and is rightly cautious in drawing any conclusions except such as are founded upon an extended series of observations.

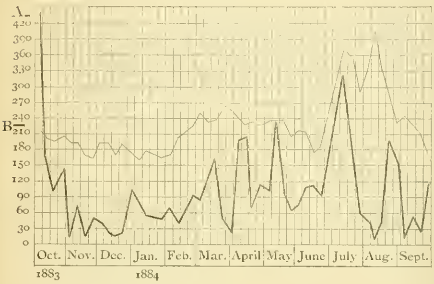


Fig. 1.

At the commencement of June 1884, Dr. Miquel, who was then in London, made some observations on the number of bacteria contained in the air of Ryder Street, St. James's. A cubic metre of this air was found to contain only 240 organisms, but this low result was probably due to the wet weather which prevailed on four out of the five days on which the experiments were conducted —the air being remarkably free from dust. In Paris at the same time the air of the Rue de Rivoli contained 360 organisms per cubic metre. Dr. Miquel would not, however, be surprised to find that the air of London was habitually fairly pure and free from organisms, owing to the proximity of the sea, and the fact that the houses of London being generally of no great height—unlike Paris—the streets are continually being swept by currents of air. The air of sleeping-apartments is very impure as regards the number of contained micro-organisms. One such room in Paris was found to contain on the average in the winter and spring of 1882, 73,540 bacteria per cubic metre, and the air of the Hôpital de la Pitié has been observed to contain 79,000 bacteria per cubic metre. In contra-distinction to these large numbers, the air over the Atlantic Ocean (Moreau and Miquel) has been found to contain from 0 to 6 bacteria per cubic metre, and the air of the higher mountains an average of only 1 bacterium per cubic metre (Freudenreich).

A considerable part of the Report is taken up with an account of researches conducted by M. Moreau into the number of organisms present in sea-air. These investigations—undertaken under circumstances of considerable difficulty on board ship, and conducted on an elaborate scale—are of much interest as bearing on the treatment of phthisis by high mountain altitudes or by sea voyages—in both cases the special object desired being to place the patient in an atmosphere free from all impurities. We will quote a few of M. Moreau's conclusions on this subject:—(1) Air taken on the coast, when the wind is blowing off the sea from a direction in which land is at a great distance, is in a state of almost perfect purity. (2) In the neighbourhood of continents, winds blowing from the land always bring an impure atmosphere; at 100 kilometres from the coast this impurity has disappeared. (3) During moderate weather the sea does not yield to the air any of its contained bacteria; during rough and stormy weather sea-air is charged with a minute quantity of bacteria. (4) The air of ships' cabins is also charged with a number of microbes incomparably greater than that of the open air at sea, but the purity of the air of these cabins increases rapidly during the first days of the voyage; later on, an equilibrium appears to be established, depending on the amount of purification of the air by ventilation and the number of occupants. (5) The air of ships' cabins is relatively very poor in bacteria; these probably are one hundred times less in number than the air of an occupied room in Paris.

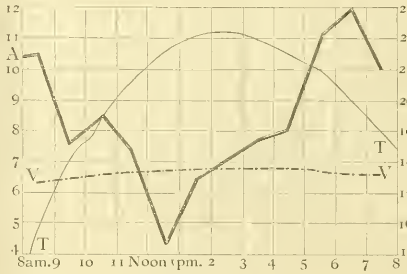

Fig. 2.

Observations have been made at Montsouris on the hourly variations in the number of bacteria contained in a cubic metre of air. These observations go to show that, contrary to the generally held opinion, the air is less pure—*i.e.* contains larger numbers of bacteria—during the morning and evening than at midday. In Fig. 2 are shown curves corresponding to proportional figures which illustrate this phenomenon, as ascertained by forty experiments. A is the bacterial curve, T is the curve representing the temperature, and V is the velocity of the wind. The lowest point of the bacterial curve is between noon and 1 p.m., two hours before the maximum temperature is reached. From 8 o'clock in the evening until midnight the number of microbes generally remains high, but decreases rapidly from midnight to 3 a.m., two or three hours before the lowest temperature is reached, and rises rapidly from 4 a.m.—when the ground and vegetation are covered with dew—until 6 a.m., when the maximum is reached. These night observations, however, are too few in number to be depended upon to give a very correct average. Rain, as has been before remarked, rapidly

purifies the air. But when the rain first commences to fall, the number of bacteria increases. This Dr. Miquel explains by supposing that many of the first drops of rain evaporate—the atmosphere not being saturated with vapour—and deliver up the bacteria they hold to the air in the neighbourhood of the earth. Later on the air is saturated with vapour, and the bacteria floating in it are carried down to the ground in the drops of rain, and by this means the air is purified.

Investigation of the organisms contained in rain show that the rain which first falls in a shower and that which falls after a period of dry-weather contain far larger numbers of bacteria than that which falls at any other times. Under such circumstances 200,000 microbes per litre is not an unusual quantity. The rain which falls during the warm months of the year—in summer and autumn—contains more microbes than that which falls in winter and spring. During the year 1883-84 the lowest monthly average was 1000 per litre in November, and the highest 6980 per litre in September. As the rain derives its organisms from the air which it purifies in its descent, we should expect the seasonal variations in the number of contained organisms in air and rain to correspond closely—as in fact they do. It is important to note that the organisms exist in the rain to a larger extent in the form of germs than in the adult state. Of 100 bacteriform organisms found in rain, on an average 60 are micrococci, 25 bacilli, and 15 true bacteria. But the numbers here given are subject to great variation in different falls of rain: the bacilli may be more numerous than the micrococci, the true bacteria being almost always fewest in number. Dr. Miquel calculates that during a year at Montsouris 4,000,000 of bacteria are carried down in the rain to each square metre of surface. This number, though not probably representing anything like the real figure, demonstrates that rain is a powerful agent in diffusing aërial bacteria and fungi. We have yet much to learn as to the part these organisms undoubtedly play when diffused into the soil, in altering or rearranging its component parts or constituents so as to render it more fit for sustaining vegetable life and growth.

The methods and apparatus employed by Dr. Miquel in his researches are very fully explained, and contrasted with other methods—especially those employed by Dr. Koch and other German observers—in terms that are not exactly those which a strict regard for international courtesy would dictate. It is somewhat of a reproach to bacteriologists that their leading authorities in all countries appear unable to keep clear of controversies which are conducted with an acrimony and animus more instructive than seemly. International jealousy would appear to lie at the root of much of this evil, and is plainly discernible in the writings of some of the ablest masters of the science.

THE RECENT VOLCANIC ERUPTION IN NEW ZEALAND

UNTIL the report of a trained geologist has been received we must be content with the narratives, often conflicting, of the surveyors and of the Press correspondents who hurried to the scene of the great catastrophe that has recently devastated the wonderland of New Zealand. In the meantime, however, it is possible from the various accounts to trace the leading features of the eruption, and to note their resemblance to those of other recorded volcanic outbursts. It is impossible not to be struck with the analogy between the phenomena exhibited last June in New Zealand and those that accompanied the great Vesuvian eruption in the first century of our era. In both instances a mountain which had never been known to be an active volcano suddenly exploded with terrific violence, filling the air with ashes and stones. At each locality there were the premonitory earthquakes, the thick black pall of volcanic cloud hanging over the mountain, the descent of dust, sand, and hot stones, the discharge of mud, with, so far as known, no outflow of lava, and the overwhelming of an inhabited district under a deep covering of loose volcanic debris.

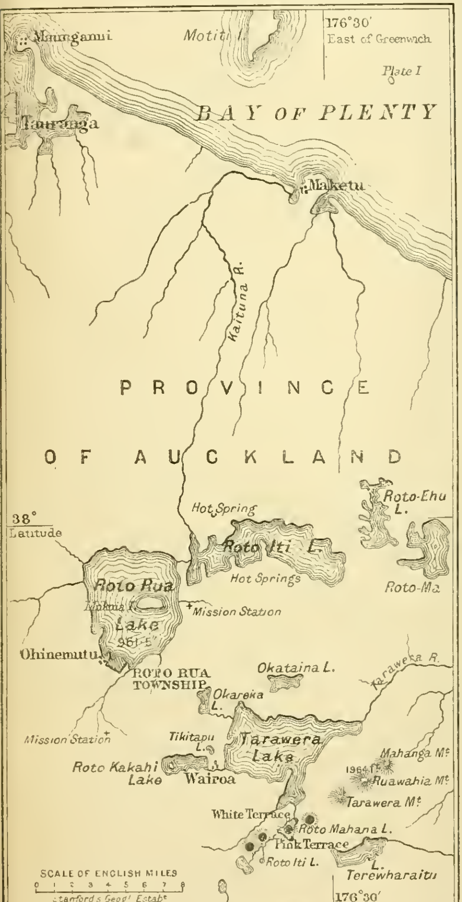
In a region so subject to earthquake shocks as that which crosses the centre of the North Island of New Zealand in a north-east and south-west direction, it was natural that no special attention should have been given to any greater frequency or violence of the shocks before the date of this volcanic eruption. But no doubt facts bearing on this subject have been noted by local observers and will in due course be published. From the newspaper accounts, indeed, there would appear to have been various precursory indications which in the light of subsequent events may not have been without importance. It is said, for instance, that the extinct volcano Ruapehu, the highest peak in the North Island, which since the discovery of New Zealand has never been known to manifest any activity, began to steam at the top some three weeks before the eruption. A fortnight previous to the catastrophe a wave 3 feet high suddenly arose on the Lake Tarawera, lying at the foot of the mountain of the same name, and in the very focus of the subsequent disturbance, and washed the boats out of the boat-houses. Doubtless there were other premonitory symptoms, besides earthquake activity, of the approaching event, though only a few days before their destruction, the famous White and Pink Terraces were visited by a party of tourists who observed no unusual vigour in the hot springs there, nor any indication whatever that these fairy-like deposits were so soon to be the theatre of violent volcanic energy.

About half an hour after midnight on the morning of June 10 the earthquake shocks that are familiar to the inhabitants of the Lake District assumed an altogether unusual vigour and frequency. At the settlement of Wairoa, which is about five miles from the warm lake and sinter terraces of Rotomahana, the ground shook violently for an hour or more, the more powerful shocks following each other at intervals of about ten minutes. The alarmed inhabitants, startled from sleep, ran out of their houses or clung to each other inside for mutual assistance and encouragement. At last, a few minutes after 2 a.m., a shock of exceptional severity was followed by a deafening roar, and suddenly what is described as a "pillar of fire" rose up from the crest of the mountain range some five or six miles eastward on the opposite side of Lake Tarawera. The top of Mount Tarawera (about 2000 feet high) had been blown into the air, leaving a huge chasm on the flank of the mountain. The glow of the white-hot lava in the interior ruddied the sky for miles around. Thousands of blocks of glowing lava described as "fire-balls" were shot into the air. The canopy of dark ashes that soon gathered over the mountain and spread out for miles around became the theatre of a violent electrical storm. It seemed to be torn asunder with incessant flashes of lightning, and the continuous peals of thunder, mingling with the bellowing of the volcano, increased the terror of the night.

That an eruption should ever take place from the three huge truncated cones that frown over Lake Tarawera was not regarded by geologists as a future probability. They had been extinct even from the times of early Maori tradition. To their solitary and mysterious summits the natives had probably for centuries been accustomed to carry their dead. The bones of many successive generations lay bleaching on that high lonely plateau, which had thus come to possess a peculiar sanctity in the eyes of the Maoris, who would not willingly allow a white man to approach it. Not only were these great cones to all appearance extinct, but the volcanic action of the whole district was of that type of waning energy which geolo-

gists have called the "solfatara stage." New geysers might break out, rivalling or even surpassing those already active in the district, and the orifices of eruption might shift from place to place, involving considerable local disturbance in their transference; but no one anticipated that in this district a great explosion, like the most gigantic outburst of Vesuvius, was likely to occur.

The magnitude of the explosion may be inferred from



NEW CRATERS, thus

several facts which appear in the newspaper reports. An observer at New Plymouth, on the west side of the island, 150 miles from the scene of the disaster, saw the column of ashes rising far into the air, and computed its height to be not less than 22,000 feet. The noise of the explosion is said to have been heard at Christ Church, a distance of some 300 miles. The ashes fell over a vast area of land and sea to the north and east of the vent of discharge. Vessels sailing even 130 miles away found the air thick with fine dust, which settled on their decks. Near the scene of the explosion the depth of accumulated ashes, still quite hot, was found by some adventurous explorers, seeking to succour the poor Maoris, to be not less than 20 feet. At a distance of 30 or 40 miles the deposit was still several inches thick, so stupendous must have been the amount of rock blown into powder by the great explosion of Tarawera.

The materials ejected from that mountain appear to have consisted mainly of loose fragments of lava, cinders, ashes, and fine dust, with vast quantities of steam, while not improbably hot water and mud issued from the flanks of the volcano. So far as can be gathered from the narratives, there was no emission of lava, though, from the "flames" and "fire-balls" so generally referred to, it may eventually be found that molten lava flowed out somewhere on the sides of the mountain.

Not far from the base of the volcanic cone of Tarawera lay the warm lake and sinter terraces of Rotomahana. The treacherous nature of that district has been often remarked—its steam-vents, boiling pools, hot steaming soil, and eruptive geysers, not always remaining in the same places, but apt with no warning to break out at fresh points. This weird locality has been involved in the volcanic disturbances of the region. The famous terraces have been blown into the air, and fragments of their sinter have been picked up among the dust and ashes of the surrounding country. The lake on the borders of which they stood has been ingulfed. On their site scores of mud-cones are vomiting forth stones and mud, and hurling clouds of steam into the air. New vents for the escape of steam and the outflow of volcanic mud have been opened all over the country, and the aspect of the landscape has been entirely changed. A scene of fairy-like beauty has been transformed into one of loathsome desolation. Even if the volcanic activity calms down and the sinter springs can recommence their work of deposition, many generations must pass away before they can build up again such terraces as have been destroyed. The new features of the country will no doubt still prove attractive to tourists, but the marvellous staircases of Te Tarata are a dream of the past.

Among the features of the eruption on which it is to be hoped that light will be thrown by the more detailed investigations of experts are the source and behaviour of the mud that overwhelmed the settlement of Wairoa. From the narratives of the survivors, showing that the houses were crushed in from above, the mud seems to have descended through the air upon the district, mingled with ashes and stones. Rain fell during the night, but the mud could hardly have been formed in the air by the mixing of the rain and dry ashes. It appears to have come down as liquid mud and was no doubt ejected as such from some neighbouring vent. The orifice of eruption could scarcely have been the great cone of Tarawera; more probably there were many vents not only at Rotomahana, but nearer to Wairoa, by which a large amount of mud was discharged over the surrounding district.

Another question that will no doubt receive careful consideration relates to the movements of the air during the time of the eruption. Barometric observations at Rotorua and at places on the opposite sides of the island will be of much interest. From the newspaper accounts it is clear that a great atmospheric disturbance accompanied the eruption. About an hour after the great explosion a gale suddenly arose in the Rotorua and Wairoa district, and blew with such fury as to uproot and prostrate immense numbers of trees, and to strip off leaves and branches from those that were left standing. At Rotorua the direction of the hurricane was towards the scene of volcanic activity, as if the air were being drawn into the vortex caused by the explosion. A few hours later the gale as suddenly ceased and then ashes began to fall, borne northwards by some upper current of air. We

have yet to learn how far these atmospheric movements were connected with or independent of the eruption.

There are some excellent geologists in New Zealand who have now a rare opportunity of investigation. No mud-eruptions at all comparable in magnitude to those of this summer in New Zealand have ever been known. The connection of these with the explosion of Tarawera, the relation of the latter to the lava-reservoir inside, the nature of the so-called "flames" and "pillar of fire" so conspicuous on the night of the eruption, the sources of the "fire-balls," and many other details, offer a wide and most interesting field for the colonial observers. Geologists all over the world will await with much interest the publication of their investigations. ARCH. GEIKIE

NOTES

THE honour of knighthood has been conferred on Mr. Philip Magnus, the head of the City and Guilds Technical Institute at South Kensington.

LAST Saturday a banquet was given to M. Chevreul by French students to celebrate the one hundredth anniversary of his birth.

THE death is reported on June 22 of Dr. H. F. Hance at Amoy, at which place he was Her Majesty's consul. Although no independent work bears Dr. Hance's name, he has done more than any other man to make us acquainted with the flora of China, both of the empire and of the British colonies. His contributions to botanical literature are to be found in periodicals, very largely in Trimen's *Journal of Botany;* and the number of species described by him for the first time is very great. He was a contributor to the herbaria at the British Museum and at Kew. It is to be hoped that his herbarium will be brought to London and deposited where it can be consulted, and his types readily compared with those of other authors. A full synonymic catalogue of all the known Chinese plants is now in course of publication by Messrs. Forbes and Hemsley, and is greatly needed.

UNDER the energetic management of Dr. Adolph Bastian the Administration of the Berlin Royal Ethnological Museum has commenced to publish a series of original communications explanatory of the varied contents of that superb collection. According to the present programme four parts of about 60 large octavo pages each, with two or more plates of illustrations, will be issued yearly by the Berlin publisher, W. Spemann, at the price of 16 marks, or 4 marks each. Judging from the three parts, which have already appeared for the year 1885–86, the series promises to develop into a vast encyclopædia of anthropological subjects. Many of the communications constitute in themselves more or less exhaustive essays on special branches of ethnology, and to some of them a peculiar value attaches, because contributed by the collectors or observers themselves. Such, for instance, is the paper on funeral rites in the Pellew Islands, contributed to the first number by the traveller, Kubary, who has spent many years in the Oceanic regions, and made a special study of the Polynesian and Micronesian islanders. The same number contains a report on Richard Rohde's expedition to the Paraguay and Brazil (Matto Grosso) in 1883–84, followed by the traveller's account of the Bororo and Guato tribes in the Upper Paraguay basin. Of great value is Dr. O. Finsch's paper in Part II. on the ethnological collections from the South Sea Islands, some 3000 objects, of which more than half found their way to the Berlin Museum. The importance of securing specimens from this region before it is too late is well shown by the experience of this traveller, who on revisiting New Britain in 1884-85 was no longer able to procure several objects which were readily obtainable three years previously. Others, such as wood-carvings, are now "manufactured" in New Ireland "for the trade," the natives finding good customers amongst the crews of passing ships. This paper is followed by the explorer Grabowski's description of nearly 200 objects from South and East Borneo, many extremely rare, if not quite unique. Dr. Bastian concludes a characteristic essay at the end of Part III. with the words: "So walte ein Jeder seines Amtes,—und uns ist die Aufgabe zugefallen,—Das rechtzeitig in Sicherheit zu bringen, was morgen schon verloren sein mag."

IN the July number of the *American Journal of Science*, Prof. Rockwood, jun., of Princeton, publishes a paper (the fifteenth of the series) on the earthquakes of North and South America for the year 1885. The writer again attempts to assign to each earthquake a grade of intensity, based where possible upon the character of the physical phenomena reported. Where no such information was available the estimate is based on the phraseology of the original report, taking into account the probable intensity of an earthquake in the locality in question. There is, as Prof. Rockwood recognises, a large element of uncertainty in these estimates, "but at least they are the best that can be made now, and better than any one else could make at a later date and without access to the original reports." This last consideration alone appears to us to justify the attempted classification. A large proportion of the American earthquakes of the year occurred in California, and accordingly a small outline earthquake map of that State for the year is given. The whole list contains 71 items: 34 belong to the Pacific coast of the United States, 9 to the Atlantic States, 8 to the Canadian provinces, 5 to New England, 3 to the Mississippi valley, 5 to South and 2 to Central America.

WE may also take this opportunity of referring to the same writer's annual account of the progress in vulcanology and seismology for 1885, published in the Smithsonian Report. Most of the incidents recorded, and papers and other publications referred to have from time to time been described or reported in our own columns, and it is therefore only necessary to say that in this as in previous years the summary shows great care and industry, and should be an invaluable *vade mecum* to all interested in the study of these phenomena.

THE United States Commissioners are still continuing their labours in the direction of acclimatising flatfish to American waters, which are nearly as well suited to the *Pleuronectidæ* as English waters. Several attempts have been made to transmit them from our shores alive, but hitherto with little success. Information has, however, reached us to the effect that fifty soles during last month were sent by the Derby Museum authorities at Liverpool, twenty-five of which reached their destination alive. Prof. Baird, the Chief Commissioner, states that the fish are in a thriving condition and feed well. They have been placed in a suitable habitat at Washington Station, and are being watched with special care. The soles, which are about three inches long, were transmitted in glass globes attached to the ceiling of the cabin of the s.s. *Britannic*. This method minimises the risk of injury to the fish through the oscillation of the vessel, as the receptacles, being swung, move backwards and forwards with the motion of the steamer. The National Fish Culture Association intend forwarding to America another consignment of flatfish next month in order to assist the operations of the Commissioners. The sole is a very delicate fish, and cannot withstand the strain of protracted journeys, which makes it very difficult to transmit.

MESSRS. J. B. LIPPINCOTT AND CO. have in the press a "Manual of North American Birds," by the eminent ornithologist, Prof. Robert Ridgway, Curator of the Department of Birds, Smithsonian Institution, Washington, D.C. The author has had

exceptional advantages for the preparation of a treatise of this character, arising from his own field experience, as well as his connection with the National Museum, and the free access which has been granted him to various other public and private collections of birds, both in this country and Europe. The work is to contain some 425 illustrations suitably executed, and will conform to the geographical limits, classification, numeration, and nomenclature adopted by the American Ornithological Union.

ACCORDING to an official notification of the trustees of the "Schwestern Fröhlich Stiftung" at Vienna certain donations and pensions will be granted from the funds of this charity this year in accordance with the will of the testatrix, Miss Anna Fröhlich, to deserving persons of talent who have distinguished themselves in any of the branches of science, art, or literature, who may be in want of pecuniary support either through accident, illness, or infirmity consequent upon old age. The grant of such temporary or permanent assistance in the form of donations or pensions is, according to the terms of the foundation deed, primarily intended for Austrian artists, literary men and men of science, but in which however foreigners of every nationality—English and others—may likewise participate provided they are resident in Austria. Donations will be granted to artists and men of letters and science for the purpose of completing their studies, and for the execution or publication of a certain specific work, and also in cases of sudden inability to work. Pensions are being granted to artists and men of letters and science who, in consequence of old age, illness, or other misfortunes, have been placed in a position of want. The applications addressed to the trustees (das curatorium) must be transmitted to the president's office of the Common Council of the City of Vienna (an das Präsidial-Bureau des Wiener Gemeinderathes Neues Rathhaus) before August 31, 1886, through the Austro-Hungarian Embassy in London, 18, Belgrave Square, S.W., where also further particulars of the terms and conditions of the foundation deeds, &c., can be obtained.

THE fifth Circular of Information for 1885, published by the United States Bureau of Education, is a very exhaustive treatise upon physical education. It directs attention to the four different ideas of manly excellence: the Greek, or æsthetic; the monkish, or ascetic; the military, or knightly; and the medical, or scientific. The recent war popularised the third in America, and reports of work of that class are accordingly to be found here. The teachings of the fourth, down to the most recent day, are of course the essence of the paper, and more than once attention is called to the great tendency of such teaching to return to the old standards of the first. In England, and still more in America, the oldest colleges and schools were founded with the principal object of educating a clergy, and accordingly were imbued with the spirit of the second—an important result of which has been that the games which occupy so much of the thoughts and the time of the students have hardly ever been recognised by the authorities, who have quite recently been forced to take them under their control to prevent abuse. It is felt now how important it is that games and exercises should be supervised and made a part of education, to be carefully controlled by a competent M.D., who shall be one of the Faculty on a par with the other masters. Rugby football is condemned by the great Harvard University as a "brutal and dangerous" game. Many strong objections to much that attends public games are recounted, and many careful restrictions on games generally have been agreed to by the highest authorities, both scholastic and medical. The code and the books of Mr. Maclaren, of Oxford—a prophet too little honoured in his own country—are highly praised, but Germany carries the palm for science and laborious thoroughness. The manual labour which has been so successful in the lower-grade schools is naturally not found popular in the colleges. A warning voice is raised against the high pressure at which girls live both at work and pleasure, and the necessity of more regular rest and exercise is insisted upon. A large part of the Circular consists of plans and elevations of gymnasiums, useful to both schoolmasters and architects.

THE labours of a curator who undertakes the first setting in order of the raw material of a museum in a new building are fully disclosed in the Report of the Nottingham Free Natural History Museum, which published the works of Mr. J. F. Blake, the Superintendent. And it can be no small labour to which he has devoted himself, even though extending over five years; comprising, as it does, the naming and re-naming of 11,400 specimens of every class of natural production hitherto kept with very little care; the supplementing them, as opportunity offered, with important desiderata till the total number of objects exhibited has increased to 21,960; the preparation of maps showing the geographical distribution of the animals near which they are placed; the pictorial mounting of specimens of birds and of birds' nests; and the specially important duty of a local museum of getting together as complete a local collection as possible. At the same time we regard it as a most wholesome symptom in the case that Mr. Blake is by no means satisfied with his achievements, and we wish him more rapid progress in all his present and future undertakings on behalf of the Museum.

AMONG recent contributions to natural-history literature, attention is due to an interesting work by the eminent Norwegian naturalist, Leonhard Stejneger, published in the United States under the title of "Results of Ornithological Explorations in the Commander Islands and Kamtschatka." In this work, which is illustrated by coloured plates, the author describes upwards of 140 species, all of which were collected or observed by himself during his various visits to Behring's Sea and the neighbouring coast-lands and islands. The main results of these expeditions had previously appeared in the *Bulletins* of the U.S. National Museum, in the Ornithological Department of which institution Mr. Stejneger holds the post of Assistant Curator, while he has also from time to time supplied *Naturen* with pleasantly-written popular reports of his voyages and observations, and to these we have more than once had occasion to make favourable reference. As, however, both these sources are inaccessible to the general reader, we welcome with great satisfaction the present comprehensive English exposition of Mr. Stejneger's most recent contributions to the branch of science which he so successfully cultivates. Within his own province he has, moreover, been doing good service to popular science as compiler of the ornithological portion of the American "Standard Natural History," published at Boston by Messrs. Cassino and Co. In Mr. Stejneger's original contributions to this work, which claims to be based on the most recent results of science, he has been able by his own observations to make various additions to, and corrections of, the statements of Brehm, who has hitherto been trusted as our principal authority regarding North European and American ornithology.

DURING a severe thunderstorm which passed over Central Norway last week a remarkable example of the power of lightning was witnessed. In a field at Löiten a fir-tree 80 feet in height was struck by lightning some 12 feet from the ground, with the effect that the tree was cut in halves and the upper portion—about 60 feet in length—thrown a distance of several yards. The most curious part, is, however, that the surface of the detached part is as smooth as if the tree had been sawn through, whilst that of the stump remaining in the ground is jagged, charred, and splintered to the root. The ground around the tree is furrowed in all directions, one being several feet in

width and depth, and extending for some 10 yards. A spruce-tree close by shows a furrow an inch in width running from a height of 6 feet down to the root.

ON Thursday night, at 11.30, M. L'Hoste crossed from Cherbourg in a balloon, alighting in the neighbourhood of London at 6.30 on Friday morning. M. L'Hoste had a small sail to assist in directing the balloon, and an apparatus for letting down into the sea to draw water into the balloon to act as ballast. He was accompanied by M. Mangot, the astronomer. The highest altitude attained was 3600 feet, and the lowest temperature observed 7° C.

THE additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, presented by Mrs. Barrington; a Blue-faced Amazon (*Chrysotis æstiva*) from Brazil, presented by Mrs. J. Fletcher; an Aldrovandis Skink (*Plestiodon auratus*) from North Africa, presented by Mr. R. J. M. Teil; two Grey Parrots (*Psittacus erithacus*) from West Africa, deposited; a Sea Eagle (*Haliaetus* ——), a Masked Weaver Bird (*Hyphantornis personata*) from Africa, a Short-eared Owl (*Asio brachyotus*), European, a Hyacinthine Macaw (*Ara hyacinthina*) from North Brazil, two Blanding's Terrapins (*Clemmys blandingi*) from North America, two Indian River Snakes (*Tropidonotus quincunciatus*) from India, purchased; two Triangular Spotted Pigeons (*Columba guinea*), a Geoffroy's Dove (*Peristera geoffroii*), four Brazilian Teals (*Querquedula brasiliensis*), five Slender Ducks (*Anas gibberifrons*), two Chilian Pintails (*Dafila spinicauda*), two Wild Ducks (*Anas boschas*), a Himalayan Monaul (*Lophophorus impeyanus*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *AUGUST* 8–14

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 8

Sun rises, 4h. 37m.; souths, 12h. 5m. 25·3s.; sets, 19h. 34m.; decl. on meridian, 16° 6′ N.: Sidereal Time at Sunset, 16h. 43m.

Moon (two days after First Quarter) rises, 14h. 45m.; souths, 19h. 25m.; sets, 0h. 1m.*; decl. on meridian, 16° 41′ S.

M signifies maximum; *m* minimum; m_2 secondary minimum.

Meteor Showers

The principal shower of the week is that of the *Perseids*, R.A. 43°, Decl. 56° N. The maximum occurs on August 10, but many meteors from the same radiant are usually seen on the nights both immediately preceding and following that date. Meteors are frequently seen also from neighbouring radiants, *e.g.* near the Pleiades, R.A. 55°, Decl. 26° N.; near Capella, R.A. 68°, Decl. 46° N.; near ν Tauri, R.A. 55°, Decl. 7° N.; and from Lynx, R.A. 96°, Decl. 71° N. A radiant from α Pegasi, R.A. 345°, Decl. 15° N., is also active at this season, which is usually the most prolific of the year.

THE SCIENTIFIC DEVELOPMENT OF THE COAL-TAR COLOUR INDUSTRY[1]

THE subject on which I propose to address you this evening has been brought under the notice of the Society of Arts on former occasions, and was only last year thoroughly treated of by Dr. W. H. Perkin, the pioneer of this branch of manufacture, in his Presidential Address to the Society of Chemical Industry. It has, moreover, quite recently furnished materials for a lecture at the Royal Institution by Sir Henry Roscoe, so that I feel in some measure obliged to apologise for again bringing forward a topic upon which it may appear to chemists that nothing particularly new remains to be said. Having, however, been intimately associated with this branch of chemical industry for many years, I have had exceptional opportunities of watching its development, and of forming ideas upon the causes of its progress, which may justify my engaging your attention upon the present occasion.

The manufacture of coal-tar products is a subject which offers distinct advantage for popular treatment, both on account of the practical utility of the products, and the striking and beautiful colour phenomena which they present. But I do not propose now to avail myself of these advantages, because I think there is a more serious aspect of the subject than the mere enumeration of the names, chemical formulæ, and mode of preparation of the recently discovered products. I must take it for granted that those present this evening are familiar with the fact that out of coal-tar there are obtained series of hydrocarbons from which are prepared nearly all the dye-stuffs at present in use; that the introduction of these artificial colouring-matters has revolutionised the tinctorial industries, and that the tar of gas-works, which was formerly a waste product and a nuisance, is now a valuable source of revenue to the gas companies. It is, doubtless, known to you also that, besides colouring-matters, there are obtained from the same hydrocarbons artificial perfumes, and drugs which rival quinine in efficiency; and that quite recently a substance has been discovered by Dr. Fahlberg, which goes by the name of "saccharine," and which is stated to possess 220 times the sweetening power of cane sugar.[2] But I must content myself by merely pointing to such discoveries as triumphs which the chemist, by his "so potent art," has achieved in recent times, because I want to bring home to English manufacturers one particular point in connection with this industry, and the Chemical Section of the Society for the Encouragement of Arts, Manufactures, and Commerce seems to me to be the right place for so doing. It cannot be denied that the coal-tar industry has for some years past been migrating from this country, the land of its birth, to the continent of Europe. Of the causes of this decline assigned by Dr. Perkin and others who have expressed opinions upon the subject, I do not now propose to touch upon those which may be considered as purely politico-economical

[1] A Paper read at the Society of Arts by Prof. R. Meldola, F.R.S., F.C.S., F.I.C., on May 13, 1886.

[2] The substance referred to is an anhydro-derivative of orthosulphaminebenzoic acid having the formula

$$C_6H_4 < \begin{matrix} CO \\ SO_2 \end{matrix} > NH.$$

For details, see a paper by I. Levinstein, *Journ.* Soc. Chem. Ind., Feb. 1886, p. 75. Also the original communications in the *American Chemical Journal*, vol. i. pp. 170 and 426, and vol. ii. p. 181. For an investigation of the physiological action see the *Archivio per le scienze mediche*, vol. ix. No. 22, p. 407 (Turin, 1886).

ones, such as Free Trade, the Patent Laws, or the available energy of a British as compared with a German workman under the stimulus of a certain amount of weekly wage. These and kindred questions—such as the cost of railway carriage, or the relative ideas of "making a manufacture pay" which may exist in the British and Teutonic minds—have, doubtless, a most important bearing upon the main subject, but their discussion would occupy far too much time, and would, moreover, be out of place in this Section. I might even go so far as to express a private belief that if this portion of the subject were handed over for legitimate treatment by economists, the conclusions arrived at (if any) would hardly be commensurate with the amount of discussion which would be evoked. In fact, it appears to me that although, in a general way, each of the causes mentioned must be a factor in determining the success of any branch of manufacture, it is quite impossible to assign its true value to each of these factors; and in the case of the present industry I am persuaded that it is now a question of chemical and not of economic science that is pressing for consideration.

It will, I think, be conceded that the manufacture of coal-tar products is *par excellence* the most scientific of the chemical industries. This high position may fairly be claimed for the industry when we consider the number and complexity of the products, the delicacy of many of the reactions employed, the special arrangements of plant required, and the intimate knowledge of the chemistry of the aromatic compounds which the colour chemist must at the present time possess. Moreover, the industry is of comparatively recent growth—it has been born and has reached its present development within the last thirty years, so that the successive phases of its evolution can be clearly traced. For these reasons the subject is well calculated to throw light upon the general question of technical chemical education, a question of which the importance to the country at large now bids fair to become duly recognised.

In treating of the industrial development of a branch of chemical manufacture, it is important that we should begin with a distinct idea of the products themselves. I must claim the indulgence of chemists if at this stage I find it necessary to go over somewhat old ground, and to state facts with which so many are familiar. It would, of course, be quite impossible to give, on the present occasion, anything like a complete chronological list of the various colouring-matters, and it would be equally impossible for me to enter into the discussion of the chemical structure of the beautiful compounds which are now to be met with in the market. If, later on, I find it necessary to enter into questions of chemical constitution, it will be chiefly with the object of illustrating general principles by appealing to particular cases. In the brief historical sketch which I now propose to lay before you, I shall mention only those discoveries which may be considered to mark distinct commercial epochs in the development of the industry. The successive steps in this development will furnish us with one of the most striking illustrations of the utilisation of scientific discovery for industrial purposes, and the reaction of industry upon pure science.

Commencing in the year 1856, the foundation of the coal-tar colour industry was laid by Perkin, by the discovery of mauve, a violet dye, obtained accidentally in the course of an investigation having for its object the preparation of quinine by an artificial synthesis. In 1860, magenta, which had formerly been made in small quantities by expensive processes, was rendered a product of the first order of commercial importance by the discovery of the arsenic acid process by Medlock and E. C. Nicholson simultaneously. During this same year phenylated blues were first produced by Girard and De Laire, by the action of aniline upon magenta base at a high temperature. These blues had but a limited application owing to their insolubility, and their value was enormously enhanced by Nicholson's discovery, in 1862, that these colours could be converted into soluble sulphonic acids. The first azo-colour, amidoazobenzene, a basic yellow dye, was introduced in 1863 by the firm of Simpson, Maule, and Nicholson, under the name of "aniline yellow." In this same year the methylic and ethylic derivatives of magenta were manufactured by the same firm under the name of "Hofmann violets," in honour of their discoverer. "Azodiphenyl blue," the first of the colouring-matters now known as indulines, and Manchester yellow, appeared in 1864; and in 1866 "Bismarck brown" (triamidoazobenzene) was first manufactured at Manchester. The same year (1866) was marked by the introduction of Coupier's nitro-benzene process for the manufacture of magenta. In 1868 Graebe and Liebermann gave to the world their great discovery of the chemical constitution of alizarin, and in the following year the manufacture of this colouring-matter from anthracene was commenced. The first members of the great family of the "phthaleïnes," viz. galleïn and fluoresceïn, were discovered by Baeyer in 1871; and the first technical application of this discovery was made in 1874 by Caro, who introduced the beautiful pink tetrabromfluoresceïn into commerce, under the name of "eosin." Diamidoazobenzene was discovered by Caro and Witt independently in 1875, and was introduced into commerce by the latter as "chrysoïdine." A great impetus was given to the technical production of azo-colouring matters by this discovery, the naphthol oranges and other "tropœolines," fast-red, the ponceau scarlets, &c., appearing in 1878. Methylene blue and acid magenta were introduced by Caro in 1877, and in the same year the old and fugitive "aniline yellow" was converted into a valuable acid yellow by Grässler, who patented a process for converting the base into a sulphonic acid. Malachite green was introduced in 1878, and in 1879 the first member of the now important group of secondary azo-compounds appeared under the name of Biebrich scarlet. It is these secondary azo-scarlets, and especially the "croceine scarlets" (discovered in 1881) which are exterminating the cochineal industry. The year 1880 was marked by the brilliant discovery of the constitution of indigo, and the synthesis of this colouring-matter by Baeyer, a discovery which is none the less a triumph of synthetical chemistry because the manufacture is not at present successful from a commercial point of view. Indophenols were introduced by Koechlin and Witt in 1881, and in 1883 appeared Caro's first patent for the production of colouring-matters of the rosaniline group by the method of "condensation" with phosgene gas, in the presence of suitable condensing-agents.

This chronological record comprises nearly all the chief colouring-matters from coal-tar which are, or have been, of industrial value. It is important to note that the list, even as it stands in the form of a bald statement of facts in chemical history, reveals the existence of that fundamental law of the "survival of the fittest." Old products have been displaced by newer ones, as fresh discoveries were made, or processes improved, and to the chemist it is of interest to observe how this development of an industry has gone on *pari passu* with the development of the science itself. The moral conveyed to the manufacturer is sufficiently obvious. If we are to recover our former supremacy in this industry, we must begin by dispelling conservative ideas —we must realise the fact that no existing process is final, and that no product at present sent into the market is destined to survive for an unlimited period. The scientific manufacturer must be brought to see that present success is no guarantee for future stability, and unless he realises this position in its fullest significance, he may find the sale of his standard products gradually falling off, or be compelled to wake up to the unpleasant fact that his competitors are underselling him, owing to improved methods of manufacture.

It may appear to many that I am here simply preaching the doctrine of progress, and that the remarks which I have offered are mere truisms. Unfortunately, the facts of the case render this appeal necessary. It must never be forgotten that the coal-tar colour industry is essentially of English origin. It was Faraday who first discovered benzene in 1825; it was Mansfield who, in 1847, first isolated this substance in large quantities from coal-tar, and showed how nitro-benzene could be manufactured therefrom. The beginning of the colour industry was Perkin's discovery of mauve; and the introduction of the new colour into dyeing establishments was due to the example set by Messrs. Pullar, of Perth, in 1856. The manufacture of magenta on a large scale was the result of the discovery of the arsenic acid process by Medlock and Nicholson; and the phenylic blues were made commercially valuable by Nicholson. The first azo-colours, "aniline yellow" and "Manchester brown," as well as "Manchester yellow" (dinitro-α-naphthol) were manufactured in this country. We may thus fairly lay claim to have given to the commercial world the types of all the more important colouring-matters of the present time. If, as is certainly the case, the development of these typical products has been allowed to take place in other countries, it behoves us, as a practical nation, to inquire closely into the cause of this success abroad—a success which will appear all the more remarkable when we bear in mind that we are the largest European producers of the raw material, gas-tar, out of which the colours are manufactured,

as well as being among the largest consumers of the dyes themselves. It is estimated that the amount of tar distilled annually in this country is about 500,000 tons, and it is certain that we distil at least one-half of the whole amount of tar produced in Europe. The present state of affairs is that our competitors can afford to import the raw materials from us, to manufacture and return the colours so as to compete with us successfully in our own markets, and to undersell us in the foreign markets. The bare mention of these facts will be sufficient to indicate the existence of something requiring radical reform in our manufacturing system.

Before submitting to you the statistics of this industry which I have been able to collect, I think it desirable to make an attempt to show the inner mechanism by which chemical science has been and is being so successfully adjusted to commercial wants by our Continental neighbours. I regret exceedingly that my predecessors on this and other platforms have not left me the chance of giving a general sketch of the chemical development of the different groups of colouring-matters. In fact, I find myself suffering here from several distinct disadvantages, but I hope, with your forbearance, to make the best of the situation. It will serve my purpose equally well, or perhaps even better, to confine my illustration to one particular group of colouring-matters. The more striking achievements, such as the syntheses of alizarin and indigo, are now so familiar to chemical audiences that their repetition would be unnecessary. Equally instructive, from the present point of view would be the history of the colouring-matters of the rosaniline group, and I can only express a passing regret that time will not permit me to recapitulate the steps in the beautiful series of investigations which led to the establishment of the structural formula of rosaniline and its derivatives by E. and O. Fischer, and then to the synthesis of these colours by Caro from ketone bases. The principle which I wish to bring out may seem a strange one to a "practical" people, but I am convinced that the whole secret of success abroad is the spirit of complete indifference to immediately successful results in which the researches are carried on. I say "immediately successful" because it would of course be absurd on the part of an investigator not to take advantage of any discovery which happened to be of commercial value. But, as a general principle, the question of practical utility does not in the first place enter into the work. The great development of this and many other industries is mainly due to the complete and thorough recognition, on the part of our competitors, of the vital importance of chemical science. In this country, where the word "practical" threatens to become a reproach, we put science into the background, and attach all importance to the mere *technique* of our manufactures. If I might venture to offer an aphorism to the English manufacturer, it would be to the effect that he should look after the science, and leave the *technique* to take care of itself.

After these considerations, you will see that it is a matter of perfect indifference whether I take by way of illustration products which have been successful from a financial point of view or not. In order to give greater emphasis to the principle, I propose, however, to consider the history of some colouring-matters which have found a market value, and I select this group with the more readiness because, on the one hand, it was not treated of last year by Dr. Perkin, and, on the other hand, it furnishes a splendid illustration of the way in which these coal-tar products are being scientifically developed in the foreign laboratories.

In 1863, Mr. E. C. Nicholson discovered a basic orange colouring-matter among the by-products formed during the manufacture of magenta by the arsenic acid process. The method of isolating this substance in a state of purity was very skilfully worked out by Messrs. Simpson, Maule, and Nicholson, and the colour was introduced into the market under the name of "phosphine." This dye was the first basic orange discovered, and the advantages which it possessed for certain kinds of dyeing enabled the manufacturers to sell it at a price which helped to cheapen the cost price of magenta to an appreciable extent. The chemical composition of the substance was established in 1863 by Hofmann, who assigned the formula $C_{20}H_{17}N_3 . H_2O$, and described the base under the name of chrysaniline. Although other and cheaper basic orange colouring-matters have since been discovered, chrysaniline still finds a distinct use; and I am informed by Messrs. Brooke, Simpson, and Spiller that the amount of this colour now sold is not appreciably less than at the time of its introduction by their predecessors. The chemical constitution of chrysaniline remained unknown till about two years ago, when the problem was solved by O. Fischer (*Berichte*, 1884, p. 203). In order to be able to follow the steps in the investigation, it will be necessary, in the first place, to go back to the discovery of another colouring-matter, called flavaniline, of which the existence was made known by O. Fischer and C. Rudolph in 1882 (*Berichte*, 1882, p. 1500). Flavaniline was produced by the action of dehydrating agents, such as zinc chloride, upon acetanilide, this fact having been observed by Rudolph in 1881, and the practical manufacture of the colour having been carried on under a patent by Messrs. Meister, Lucius, and Brüning, of the Hoechst colour-works.[1] Supplied with a large quantity of the pure crystalline material by the manufacturers, Messrs. Fischer and Rudolph established the formula of flavaniline, $C_{16}H_{14}N_2$, and showed that its formation from acetanilide might be expressed by the equation :—

$$2C_6H_5 . NH . C_2H_3O - 2OH_2 = C_{16}H_{14}N_2.$$

By the action of nitrous acid upon flavaniline a diazo-compound was produced which, by the usual method of decomposition by water, gave a phenolic derivative termed flavenol, and possessing the formula $C_{16}H_{12}N . OH$, thus proving that flavaniline contained a displaceable NH_2 group. By heating flavenol with zinc dust, a base was obtained having the formula $C_{16}H_{13}N$, and termed flavoline. This base had an odour resembling that of quinoline, and all its properties suggested to the authors that flavaniline was in reality a quinoline derivative. That flavaniline was amido flavoline was proved by nitrating the latter base, and reducing the nitro-compound, when flavaniline was obtained. In a later publication by Besthorn and Fischer (*Berichte*, 1883, p. 68) it was announced that flavenol, when oxidised by potassium permanganate in an alkaline solution, gave an acid which, on distilling with lime, furnished a base having all the characters of lepidine. By the continued oxidation of flavenol with excess of alkaline permanganate, another acid was obtained, which proved to be picoline-tricarbonic acid, and the latter, on further oxidation, gave picoline-tetracarbonic acid (*Berichte*, 1884, p. 2925).

So much for the facts; now for their interpretation. The production of flavenol from flavaniline by the diazo-reaction shows that the respective formulas of these substances are :—

$$C_{16}H_{12}(NH_2)N \qquad C_{16}H_{12}(OH)N.$$

Flavenol gave, as the first product of oxidation, lepidine-carbonic acid, of which the formula is $C_{10}H_8N(CO_2H)$, and by further oxidation it gave picoline-tricarbonic acid, of which the formula is $C_6H_4N(CO_2H)_3$. Now the C-atoms oxidised by the breaking down of the 16-carbon atom flavenol into 11-carbon atom lepidine-carbonic acid, are those C-atoms which in flavenol are associated with the hydroxyl group, because this group is no longer contained in the product of oxidation. Thus the formulas of flavaniline, flavenol, and flavoline are better expressed as :—

$$C_{10}H_8N . C_6H_4(NH_2)$$
$$C_{10}H_8N . C_6H_4(OH)$$
$$C_{10}H_8N . C_6H_5.$$

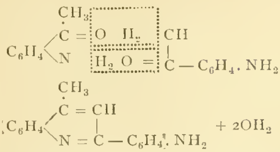
From this it appears that flavaniline is amidophenyl-lepidine, flavenol hydroxyphenyl-lepidine, and that flavoline is phenyl-lepidine.

The central nucleus of flavaniline having thus been shown to be lepidine (which is methylquinoline), the next question to be settled was the mode of formation of the colour base from acetanilide. The authors suggest that at the high temperature of the reaction, acetanilide, in the first place, becomes transformed into the isomeric orthoamidoacetophenone :—

$$\underset{\text{Acetanilide.}}{\begin{array}{c}\mathrm{H}\quad\mathrm{CH_3}\\ \mathrm{C_6H_5 . N . C : O}\end{array}} \qquad \underset{\text{Amidoacetophenone.}}{\begin{array}{c}\mathrm{CH_3}\\ \mathrm{C_6H_4}\left\langle\begin{array}{l}\mathrm{C : O}\\ \mathrm{NH_2}\end{array}\right.\end{array}}$$

By the condensation of two molecules of the amidoacetophenone with the elimination of two molecules of water, flavaniline would be produced in a manner analogous to the formation of mesitylene by the condensation of three molecules of acetone under the influence of dehydrating agents :—

[1] I am indebted to this firm for having kindly supplied me with specimens of these products for exhibition.



The accuracy of this suggestion was verified by showing that orthoamidoacetophenone is present in small quantity when the reaction is arrested as soon as the formation of colouring-matter commences; and conversely, when pure orthoamidoacetophenone was heated with zinc chloride, flavaniline was produced in small quantity.[1]

We may be permitted to pause at this stage of the investigation, before proceeding to consider the connection of this work with the constitution of chrysaniline. These results cannot but be regarded by chemists as a very beautiful piece of investigation; but the person of a "practical" turn of mind may possibly want to know what bearing they have upon the question of market value—the question which the manufacturer but too frequently considers as the only one of importance. Now it is the essence of chemical science—as indeed of all other sciences—that every discovered fact is related to other groups of facts, and although the relationship may not at once be apparent, it is only a matter of further development that is necessary in order to reveal relationships which are at present obscure on account of our imperfect knowledge. Thus, the policy of looking at a chemical product from the narrow point of view of immediate utility is not only unscientific, but it is detrimental to the interests of the manufacturer himself. Every new compound or process discovered—every structural formula established by legitimate investigation, may have an enormous influence, directly or indirectly, upon the market value of products at present sent into commerce. Our manufacturers must realise this if they wish to recover their position in the coal-tar industry, or in fact in any other chemical industry. There is no branch of manufacture so perfect as not to be open to further improvement, and until the broad spirit of scientific development is made to replace the suicidal policy of immediate utility, our position as a manufacturing nation is not likely to be improved.

In order to justify this digression by the particular instance now under consideration, we must return to the work of Messrs. Fischer and Besthorn. The discovery that flavaniline was a quinoline derivative was of importance as a principle, quite apart from any immediate value attaching to the dye-stuff itself. Up to the time of this discovery, the quinoline derivatives, with the exception of alizarine blue, had been practically of no importance in the tinctorial industries, but as a consequence of the present investigation, the question at once suggested itself whether the analogous bases of high boiling-point, which are present in coal-tar, such, for example, as acridine, might not be utilised as sources of colouring-matters. I may remind you that the fact of quinoline being an aromatic compound was first established by the researches of our Chairman this evening, Prof. Dewar, who obtained aniline from this base. In a subsequent paper on chrysaniline (O. Fischer and G. Körner, *Berichte*, 1884, p. 203), it was pointed out that in the course of his investigations upon rosaniline Fischer had observed that the former base, like rosaniline, was capable of furnishing a diazo-compound. An observation made by Claus is also mentioned, viz. the conversion of chrysaniline into a phenol (chrysophenol) by heating to a high temperature with hydrochloric acid in accordance with the equation:—

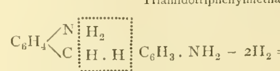
$$\underset{\text{Chrysaniline hydrochloride.}}{C_{19}H_{15}N_3 . HCl} + H_2O = \underset{\text{Chrysophenol.}}{C_{19}H_{15}N_2O} + NH_4Cl.$$

The investigation of flavaniline appears to have given an impetus to the ideas respecting chrysaniline, because of the general similarity in the properties of these two substances. In confirmation of this impression, it was found that by the oxidation of chrysophenol an acid was obtained which, on distillation with lime, gave a pyridine base. I need hardly remind you that picoline, which was obtained from the acid resulting from the extreme oxidation of flavenol, is methylpyridine. It was thus established that chrysaniline was a derivative of a quinoline base.

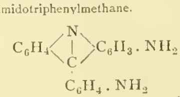
The next step in the investigation is a very important one. By decomposing the diazo-compound of chrysaniline with alcohol according to the Griess reaction, phenylacridine was obtained. Acridine is a base belonging to the quinoline series, having the formula $C_{13}H_9N$. It was discovered by Graebe and Caro in 1872 in crude anthracene. Phenylacridine accordingly possesses the formula $C_{13}H_8N . C_6H_5$; and chrysaniline appears as diamidophenylacridine, $C_{13}H_7(NH_2)N . C_6H_4(NH_2)$, because two amido groups are replaced by H by the diazo reaction. Thus the formula $C_{20}H_{17}N_3$ (first assigned by Hofmann to chrysaniline) is really the formula of the higher homologue, chrysotoluidine.

In order to explain the formation of chrysaniline during the oxidation of the materials (aniline and toluidine) in the "red melt" still, several suggestions were put forward, of which the most probable appeared to be that the base was derived from triamidotriphenylmethane, the latter compound resulting from the condensation of two molecules of aniline with one of orthotoluidine:—

$$C_6H_4\begin{cases}NH_2\\CH_3\end{cases} + 2C_6H_5 . NH_2 - 2H_2 = \underset{\text{Triamidotriphenylmethane.}}{HC(C_6H_4NH_2)_3}$$



Triamidotriphenylmethane.



Diamidophenylacridine = Chrysaniline.

The relationship of chrysaniline to the colouring-matters of the rosaniline group is thus indicated; but, tempting as is this theme, time will not admit of further digression into this field. The main point, so far as we are at present concerned, is that by means of the present investigation, we have now arrived at a knowledge of the parent substance, acridine, of which a colouring-matter more than twenty years old proves to be a derivative. By such results new fields of investigation are opened up, and direct methods for the production of chrysaniline suggest themselves. Even the practical requirements would be satisfied if it could be shown that the colour could be manufactured cheaply by a direct synthesis, instead of depending, as heretofore, upon the small and capricious secondary product of the magenta manufacture. As a matter of fact several syntheses of chrysaniline have been effected, one of which forms the subject of a patent (German Patent, 29142, April 1884) by Messrs. Ewer and Pick, of Berlin. Into the mode of preparation by this patented process I cannot now enter any further than by merely stating that nitrodiphenylamine and nitrobenzoylchloride form the starting-points, and that the specification bears the title—"Preparation of chrysaniline and other colouring-matters of the phenylacridine group." If an elaborate scientific investigation culminates in a patent, its utility will, I know, be conceded by many for whom the work would otherwise have possessed no particular interest.

The illustration which I have given is a typical example of the kind of scientific development which is being carried on by our chemical colleagues abroad, and which is being taken advantage of in the Continental factories. I do not wish to give you the impression that the particular colouring-matters dealt with are of supreme importance industrially—they are of considerable importance, but the modern history of any other colouring-matters would have been equally instructive. The beautiful researches of Bernthsen upon the constitution of methylene blue, would have done equally well had time permitted of my making use of them. It seemed to me more appropriate to this Section of the Society of Arts to give a somewhat detailed account of one particular series of investigations, rather than to take a skim over the mere surface of the enormous field which the coal-tar

[1] Just after writing this paper, a new contribution to the chemistry of flavaniline was published by O. Fischer (*Berichte*, 1886, p. 1036), from which it appears that the condensation is really between one molecule of *ortho-* and one molecule of *para*-amidoacetophenone, the latter being produced by the isomeric transformation of the ortho-compound at the high temperature employed. The constitution of flavaniline is thus definitely established as para-amidophenyl-γ-lepidine.

colour industry now offers. The case considered at any rate presents the advantage of not being too hackneyed, and this will be sufficient excuse for having made use of it.

It was stated at the commencement of this paper that there is reason to believe that our supremacy in the coal-tar colour industry has, for some years, been declining, and I have further expressed my belief that the chief cause of this falling off is the subordinate position given to chemical science in this country as compared with the status of this science abroad. Whether this explanation be accepted or not, the fact of the decadence of the manufacture remains, and I am in a position to bring this unpleasant truth home to our countrymen by a strong body of evidence. It must be borne in mind that the decline of any industry cannot be measured by the absolute weight of the products turned out annually, because the demand for the products in question may be on the increase, and we may be actually producing a greater weight of colours now than we were during our most successful period. The whole question is a relative one—it is simply how much material are we now turning out as compared with the amount produced by our competitors—what proportion of coal-tar products do we supply for our own and foreign consumption? In order to answer this question with some approach to numerical exactness, it occurred to me that the most trustworthy information could be obtained from the consumers themselves; and through the kindness of Mr. Robert Pullar, of Perth, and Mr. Ernest Hickson, of Bradford, I have been enabled to put myself into communication with several of the representative dyeing and printing establishments of this country. The facts obtained, as showing the actual state of the industry at the present time, appear to me of sufficient interest to be given here in some detail. I may take the present opportunity of stating that my application for statistical information has been most courteously responded to by the various firms, to whom I have great pleasure in returning my thanks.

Edward Ripley and Son, of Bradford, perhaps the largest dyers of piece-goods in the kingdom, inform me that during the year 1885 they used 86½ per cent. of foreign coal-tar colours, and 13½ per cent. of English make.

Walter Walker and Son, of Dewsbury, dyers of wool for rugs, mats, carpet yarn, and blanket stripes, estimate that during 1885 they used 80 per cent. of German dyes. They state that the exact proportion is difficult to estimate, so that the figure given is only approximative. Referring to their larger consumption of foreign colour they state:—"It is very discouraging to have to do this and send the trade out of our country, but to our own interest and advantage we have to do it."

John Newton, silk dyer, Macclesfield. Mr. Walter Newton, F.C.S., informs me that during 1885 they used 80 per cent. of foreign colour. He adds:—"The rapid advancement in the improved manufacture of some of these dyes by the Germans is the only cause of our desertion from the English colour-manufacturer."

G. W. Oldham, silk dyer, of Netherton, near Huddersfield, informs me that during 1885 he used 2000 lbs. of German dyes, 1100 lbs. of English dyes, and 800 lbs. of doubtful origin.

James Templeton and Co., of Glasgow, state that they dye as much as 30,000 lbs. of yarn (chiefly worsted) weekly, but they use only a small proportion of coal-tar dyes, all of which are of German manufacture.

Messrs. Leckie and MacGregor, of Paisley, inform me that in the west of Scotland, including Glasgow and Paisley, they are certain that at least 90 per cent. of the dyes used come from the Continent. Their own consumption of English colour only reached 6·8 per cent.

Alexander Harvey and Son, of Glasgow, yarn dyers, state that during 1885 they used 60 per cent. of German and 40 per cent. of English dyes. These figures do not include alizarin, of which they state that they used about equal quantities of German and English make. The English supply is chiefly made up of one article, "aniline salt." They add:—"We find the German makes in general of better value than the British, as our rule is, *cæteris paribus*, to give the home-make the preference."

Messrs. Manson and Henry, Glasgow, yarn dyers, state that they use only German dyes, adding that they find it to their advantage "for both cheapness and quality."

Among the largest consumers of coal-tar colours in this country are the jute dyers. As representing this department of the tinctorial industry, Messrs. James Stevenson, of Dundee, inform me that during 1885 they used only 7·7 per cent. of English colour. They have been good enough to supply the following analysis of their consumption:—

Scarlet	37 per cent.,	of which nothing	is English.
Crimson	16	,, 6·4	,,
Blues	11·5	,, nothing	,,
Oranges	11	,, ·05	,,
Greens	7	,, nothing	,,
Magenta (residues)	6·5	,, ,,	,,
Maroon	5·5	,, ,,	,,
Pink	2·75	,, ,,	,,
Brown	1·25	,, 1·25	,,
Violet	1	,, nothing	,,
Various	0·5	,, ,,	,,
	100·0	7·7	

Messrs. Cox Bros., of the Camperdown Jute Works, Lochee, state that practically the whole of the "aniline" colours used by them are of Continental manufacture.

With reference to the calico printers, the following facts have been collected:—

Messrs. Z. Heys and Sons, of Barrhead, state that during 1885 they used over 10,000 lbs. weight of colours (exclusive of alizarin), of which 700 lbs. only were of English make.

Messrs. James Black and Co., of Bonhill, Dumbartonshire, state that in their belief more than one-half of the colour used by calico printers is of foreign manufacture.

In the course of the present inquiry, it seemed desirable to obtain information concerning the consumption of alizarin, with reference to which the following statements have been received:—

Messrs. Walter Crum and Co., of Thornliebank, Glasgow, are of opinion that "the great bulk of what is used in this country is manufactured in Germany." They do not profess to be able to give actual figures having any approach to accuracy.

Mr. John Christie, of the Alexandria Turkey-Red Works, Dumbartonshire (John Orr, Ewing, and Co., states that they use only artificial alizarin in their establishment, their consumption being considerably over 2,000,000 lbs. weight of 10 per cent. paste annually. Their consumption was, in—

1880	... 98 per cent. German	... 2 per cent. English	
1881	... 99 ,, ,,	... 1 ,,	,,
1882	... 100 ,, ,,	... 0 ,,	,,
1883	... 77 ,, ,,	... 23 ,,	,,
1884	... 56 ,, ,,	... 44 ,,	,,
1885	... 47 ,, ,,	... 53 ,,	,,

Messrs. William Stirling and Sons, of Glasgow, state that their relative consumption of English and German alizarin for Turkey-red dyeing varies so much from year to year that they have no means of directly supplying useful data. This firm has, however, been good enough to make inquiries for me from a competent authority, who has furnished the following report:—

"In 1883 and 1884 I estimate that the sales in the United Kingdom amounted to a monthly average of about 530 tons, 10 per cent. (say 6360 tons, 10 per cent. per annum). Of this quantity I estimate about 30 33 per cent. was manufactured in this country. Taking 1884 alone, the figures are estimated at 566 tons, 10 per cent. per month (say 6800 tons, 10 per cent. per annum). Proportion manufactured in Great Britain, say about 30-35 per cent. In 1886 the consumption may be estimated at 550-600 tons, 10 per cent. per month (say 6900 tons, 10 per cent. per annum). Proportion manufactured in this country probably now very considerably more than 35 per cent."

This estimate of the total consumption (550-600 tons, 10 per cent. per month) is confirmed by my friend Mr. Thomas Royle, F.C.S., of the British Alizarin Company's works at Silvertown, but he is of opinion that 50 per cent. of this is of English manufacture.

By way of further confirmation, it appeared to me to be desirable to get the opinion of manufacturers themselves, and although this has been a matter of considerable difficulty, I am able to give some kind of an estimate. Mr. Ivan Levinstein, of Manchester, estimates that Germany produces:—

Colours derived from benzene and toluene, six times more than England.

Colours derived from naphthalene, seven times more than England.

Colours derived from anthracene, five times more than England.

The average production of Germany is thus about six times that of this country. Mr. W. A. Mitchell, of the firm of W. C. Barnes and Co., Phœnix Works, Hackney Wick, informs

me that of some 159 tons of "aniline" dyes which passed through their hands as agents last year, 95 per cent. were of Continental make. With reference to the two chief raw materials, benzene and aniline, this same firm estimates that about 75 per cent. of the whole quantity of these products made in England goes to the Continent.[1]

The facts and figures which I have now laid before you must be left to tell their own story—time will not permit me to attempt any analysis of them. The evidence collected will at any rate give a much more forcible idea of the true state of the coal-tar colour industry in this country than has hitherto been attempted, and if this evidence goes against us as a manufacturing nation, it is all the more desirable that our true position should be realised. I find that it is almost impossible to give a correct numerical expression in pounds sterling for the annual value of this industry to the country, as the estimates vary within very wide limits. According to Dr. Perkin, whose opinion on this matter will perhaps carry the greatest weight, the value of the annual output is between 3,000,000*l.* and 4,000,000*l.* That the industry is one of considerable importance on the Continent may be gathered from the official returns relating to the German exports. For the following figures I am indebted to Dr. H. Caro, of the "Badische Anilin und Soda Fabrik," Ludwigshafen on Rhine:—

Exported from Germany, from January 1 *to December* 31, 1885

Alizarin paste (? per cent.)	4283	tons
Aniline and intermediate products ...	1713	,,
Aniline, &c., colours	4645	,,

Dr. Caro adds that it is generally believed that about four-fifths of the entire German production are exported.

The magnitude of this branch of chemical industry abroad will be gathered from the fact that a German factory of about the third magnitude consumes at the present time between 500 and 600 tons of aniline annually. According to information recently furnished to me from the two largest of the German factories, the Badische Company employ 2500 working men and officials, and the Hoechst Colour Works (formerly Meister, Lucius, and Brüning) 1600 working men and fifty-four chemists. It must, of course, be borne in mind that in these factories the products are not "aniline" colours only, but alizarin, acids, alkalies, and all chemicals required in this branch of manufacture.

The industry which has been selected for this evening's topic is thus not only an important one in itself, but for us, as chemists, its development is fraught with meaning both scientifically and educationally. In taking up this subject it has not been my desire to exalt the coal-tar colour industry to a position of undue importance, nor do I wish it to be inferred that the remarks which I have made concerning its decadence, or at any rate stagnation, in this country are applicable to this manufacture only. The failure on our part to grasp the true spirit of chemical science in its relation to our manufactures makes itself felt in every industry in which chemistry is concerned. The strength of our competitors is in their laboratories, and not, as here, upon the exchanges. It is only by showing up our weakness in each industry that the state of affairs can be remedied, and our prestige as a manufacturing country restored. If each specialist would do for his industry what I have here attempted to do broadly for the coal-tar colour industry, we should get together a body of evidence which the Royal Commissioners on the depression of trade would do well to take into consideration. We have heard a great deal of late years about the subject of technical education, but the talk has been rather one-sided. We have had utterances from those who, recognising the enormous importance of this subject to the country, have munificently endowed those institutions for the promotion of technical education which are springing up around us; we have had all kinds of schemes from those who are taking upon themselves the duties of technical educators, but it appears to me that we have not heard with sufficient distinctness the voices of those who may be presumed to suffer most from the want of technical education, viz. the manufacturers themselves. I have heard rumours of the existence of a certain class of manufacturer—let us hope a rare species—who declares that science is no use to him, and that he can get along better without it. I must confess that I never met this individual in the flesh, but I know that he exists in some of our manufacturing centres. As a species he is, however, doomed to extinction in the struggle with his competitors, and we may consider him out of court in the discussion of schemes of technical education. It is now generally admitted that the days of empiricism have passed away, and most manufacturers admit that present success and future development depend upon a proper recognition of technical, *i.e.* of applied science. But unless the manufacturers themselves speak loudly on this question, the voices of those who wish to promote scientific education may be drowned by the clamour of mere theorists.

In no other department of our manufactures is the want of technical science more felt than in the chemical industries. We not only see this in the greater development of these industries abroad, but in some of our most successful factories here—and this applies more especially to the coal-tar colour industry—foreign chemists are employed, and as I have lately been informed by a well-known manufacturer, it is even impossible to get the necessary plant properly made in this country. There is no doubt that the recondite character of the truths of chemical science, as compared with the more obvious truths of mechanics and physics, has much to do with the want of popularity of this branch of knowledge, and is responsible for the circumstance that our science is regarded with comparative indifference until some branch of manufacture is *in extremis.* In our national characteristic of being "practical," we are apt to become short-sighted in our manufacturing policy, and to recognise only actualities, to the exclusion of the potentiality conferred upon a nation by a broader scientific culture.

In conclusion, I have to express my thanks to Messrs. Brooke, Simpson, and Spiller; Messrs. Burt, Bolton, and Haywood; and to the British Alizarin Company for the fine series of specimens now exhibited. For the beautiful specimens illustrating the Continental manufacture, I am especially indebted to the Badische Anilin and Soda Fabrik, of Ludwigshafen on Rhine, and to the Hoechst Colour Works. The series of patterns dyed with known weights of fifty distinct coal-tar colours were prepared by Mr. Ivan Levinstein for the lecture recently delivered at the Royal Institution by Sir Henry Roscoe, to whom I am indebted for being able to show them on the present occasion.

[1] According to a later estimate, kindly supplied by Mr. Ivan Levinstein, the quantity of benzene and toluene used in this country amounts to about 500,000 gallons, and that used in Germany to about 2,000,000 gallons annually. About half the English production is, however, exported as aniline, toluidine, and aniline salt, while Germany converts into colouring-matters at least 1,600,000 gallons of these hydrocarbons.

DRYING UP OF SIBERIAN LAKES

THE rapid drying up of lakes in the Aral-Caspian depression, in so far as it appears from surveys made during the last hundred years, is the subject of a very interesting and important paper contributed by M. Yadrintseff to the last issue of the *Izvestia* of the St. Petersburg Geographical Society (vol. xxii. fasc. 1). Two maps, which will be most welcome to physical geographers, accompany the paper. One of them represents the group of lakes Sumy, Abyshkan, Moloki, and Tchany, in the Governments of Tobolsk and Tomsk, according to a survey made in 1784. The other represents the same lakes according to three different surveys made during our century, in 1813 to 1820, in 1850 to 1860, and finally in 1880, and it shows thus the rapid progress of drying up of these lakes. There are also earlier maps of Lake Tchany, which represent it as having very many islands (Pallas estimated their number at seventy), but they are not reliable. As to the map of 1784, no cartographer, accustomed to distinguish "nature-true" maps from fancy ones, would hesitate in recognising it as quite reliable as to its general features. It is also fully confirmed by the ulterior detailed surveys dating from the beginning of our century. It appears from this series of four maps, dating from different periods, that the drying up has gone on at a speed which will surely appear astonishing to geographers. The group of lakes consisted of three large lakes—Sumy, Abyshkan, and Tchany, with a smaller lake, Moloki, between the two latter. Lake Tchany (the largest of the three) has much diminished in size, especially in its eastern and southern parts; but the greatest changes have gone on in the other lakes. Whole villages have grown on the site formerly occupied by Lake Moloki, which had a length of twenty miles at the end of last century, and now is hardly three miles wide. Of Lake Abyshkan, which had a length of forty miles from north to south, and a width of seventeen miles in the earlier years of this century, and whose surface was estimated at 530 square miles,

only three small ponds have remained, the largest of them being hardly one mile and a half wide. The drying up has been going on with remarkable rapidity. Even twenty-five years ago there were several lakes ten and eight miles long and wide, where there are now but little ponds. Lake Tchebakly, which was represented in 1784 as an oval forty miles long and thirty miles wide, has an elongated irregular shape on the map of the beginning of our century; it measures, however, still forty miles in length, and its width varies from seven to twenty miles; while several small lakes to the east of it show its former extension. Thirty years later we find in the same place but a few small lakes, the largest of which hardly has a length and width of three miles; and now, three small ponds, the largest of them having a width of less than two miles, are all that remain of a lake which covered about 350 square miles a hundred years ago. The same process is going on throughout the lakes of West Siberia, and throughout the Aral-Caspian depression. No geologist doubted upon, but we cannot but heartily thank M. Yadrintseff for having published documents which permit to estimate the rapidity of the process. P. K.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

We understand that Mr. Granville Cole has been appointed to the Professorship of Geology at the Bedford College, London, and Miss C. A. Raisin to the Demonstratorship in Botany at the same institution.

SCIENTIFIC SERIALS

The *Journal of Botany*.—The number for July commences with the first part of an important article (illustrated), by Messrs. Roy and Bisset, on Japanese Desmids, chiefly obtained from a lake in the Island of Yesso. The majority of the forms obtained are cosmopolitan, but some of them of great rarity in Europe. There are also some new species. Papers follow on British *Rubi*, on the *Rubi* of Somersetshire, and on the flora of St. Kilda.

American Journal of Science, July.—Memorial of Edward Tuckerman, by Asa Gray. This botanist, who was born in Boston, December 7, 1817, and died March 15, 1886, was distinguished especially in the field of lichenology, to which he devoted most of his life. He was the author of a "Synopsis of the Lichens of New England, the other Northern States, and British America," of "Lichenes Americæ Septentrionalis exsiccati" (3 vols.), and many other papers on this branch of botany, in which he has left behind him no superior.—Notes on American earthquakes (No. 15), by Prof. C. G. Rockwood, jun. This fifteenth paper of the series gives a summary of such information as the author has been able to gather on the earthquakes of North and South America during the year 1885. It tabulates seventy-one shocks, classed according to their intensity as very light, light, moderate, strong, severe, or destructive. Of these as many as thirty-four occurred on the Pacific coast of the United States, where the Bay of San Francisco appears to be a chief centre of seismic disturbance.—Observations on the Tertiary and Grand Gulf of Mississippi, by Dr. Otto Meyer. The author finds no place where Grand Gulf strata overlie the Marine Tertiary, although there are two districts where strata undistinguishable from unquestioned Grand Gulf are overlain by Marine Tertiary. The Grand Gulf is not, generally speaking, a marine formation, for it contains fresh-water shells. In Eastern Mississippi occurs a thick and extended marine greensand formation parallel to the strata immediately below the Claiborne profile. Its fauna is Claibornian, but approaches the Jacksonian.—Notes on the volcanic rocks of the Republic of Salvador, Central America, by Arnold Hague and Joseph P. Iddings. This study is based on specimens gathered by Mr. W. A. Goodyear in the course of his explorations in Salvador. They are of a highly diversified character, ranging from very basic to highly acidic forms, from rocks rich in olivine to others abounding in quartz, and may be classified under the heads of basalt, pyroxene-andesite, hornblende-pyroxene-andesite, hornblende-mica-andesite, dacite, and possibly rhyolite, basalt and dacite being best represented. Nearly all have their counterpart in Nevada, although there occur many varieties in Nevada not found in the limited series from Salvador.—The genus Strephochetus: distribution and species, by Henry M. Seely. Since reporting last year the presence of the fossil sponge, *Strephochetus ocellatus*, at one or two places in Vermont and New York, the author has traced it to many other districts in those States. To the type of the genus, *S. ocellatus*, he now also adds three new species—*S. brainerdi*, *S. atratus*, and *S. richmondensis*.—Preliminary report on the geology of the Cobscook Bay district, Maine, by N. S. Shaler. This paper, published by permission of the Director of the U.S. Geological Survey, gives a portion of the general results of two months' exploring work on the shore-line of Cobscook Bay during the summer of 1884. The fossiliferous strata have a special interest as throwing light on the position of the shore-line in past times. A conglomerate apparently of the Clinton or Niagara age on the west side of South Bay seems to show that the shore in this district was not far away during a portion of the time when the Cobscook series was forming. In the age of the Perry section there is also evidence that the coast was near its present position and that the rocks exposed to erosion were chiefly of the Laurentian epoch.—On the well-sperometer, by Alfred M. Meyer. The instrument here described, with numerous illustrations, has for the last ten years been used by the author in his laboratory for the purpose of measuring the radius of curvature of a lens of any linear aperture.—On some general terms applied to metamorphism and to the porphyritic structure of rocks, by James D. Dana. The three recognised forms of metamorphism are described and characterised as (1) crystallinic; (2) paramorphic; (3) metachemic. A full terminology of porphyritic varieties is given, based in plan on such terms as *orthophyre*, *augitophyre*, &c.

Bulletin de l'Académie Royale de Belgique, May.—On the transparency of platina, by Ed. van Aubel. After ascertaining by experiment that a sheet of cobalt, iron, or nickel obtained by electrolysis on a transparent sheet of silver, is not really transparent, as is now generally assumed, the author here endeavours to settle the question as regards mirrors of platina chemically produced, that is, by a deposit of platina on a sheet of glass, and the transparency of which is admitted by Kundt. Working with a large mirror supplied by Paul Lohmann of Berlin, from whom Kundt also obtained those used by him, M. van Aubel found, by means of spectroscopic observations, that the metal of these mirrors is not really transparent, the light merely filtering through the interstices left between the particles of platina deposited on the surface.—A contribution to the study of the salts of platina, by M. Eugène Prost. The author deals especially with the action of nitric acid and of perchloric acid on platinic hydrate, and with the action of nitric acid on the precipitated bisulphuret of platina, his object being to form the so-called normal platinic nitrates, perchlorates, and sulphates. Failing to obtain these substances, he endeavoured to get double salts of normal composition by combining them with alkaline salts having corresponding acids. The results show that all the compounds thus obtained still correspond with basic platinic salts, so that it would so far appear that a normal platinic nitrate cannot be obtained.—On the unstable equilibrium of the surface-layer of a fluid, by G. van der Mensbrugghe. The absolute instability of surface-layers exposed to the free action of the atmosphere is demonstrated on theoretical grounds. From this theory the author proposes in another paper to deduce the existence of superficial tension on the free surface of a fluid, or on the surface common to two fluids, or to a fluid and solid, thence deriving a rational explanation of the phenomenon of evaporation.—On the heat of the alloys of lead and tin, by W. Spring. Continuing the researches of Ermann, Rudberg, Regnault, Wiedmann, and others, the author seeks to determine for restricted intervals of temperature the total heat of these alloys relatively to that of their constituents. Further light is thus thrown both on the constitution of these bodies, and on the question why their point of fusion is lower than that of their constituents.

Rendiconti del Reale Istituto Lombardo, June.—On some unconscious intervals in a co-ordinate series of psychic acts, by Tito Vignoli. The object of this essay is to ascertain experimentally whether in the co-ordinate exercise, or logical sequence, of thought, it sometimes happens that some of the connecting links of the argument are supplied unconsciously. Several instances are quoted, together with the author's personal experience, showing that this really is the case. It is incidentally argued that, in its complexity, the brain is a large organ of compensation, so that, if any of its parts in which special functions are localised become disturbed or injured, these may, within

certain limits, be replaced by others, immediately if the lesion be slight, gradually if serious.—A contribution to the theory of quadratic forms, by G. Morera.

July.—A case of extraordinary hirsuteness, by Prof. Giovanni Zoja. The author refers briefly to a Spanish girl observed by him at Pavia in 1881, who was above the average height, yet whose hair, when unbound, swept the ground by several centimetres. Some of the tresses measured 180 to 187·3 centimetres.—Meteorological observations made at the Brera Observatory, Milan, during the month of June.

SOCIETIES AND ACADEMIES

Sydney

Royal Society of New South Wales, May 5.—Annual Meeting.—Prof. Liversidge, F.R.S., President, in the chair.—The President stated that 27 new Members had been elected during the year, and the total number on the roll April 30 was 492. The Clarke Medal for the year 1886 had been awarded to Prof. L. G. de Koninck, M.D., of Liége, in recognition of his distinguished scientific attainments, and more particularly of his valuable contributions to our knowledge of the Palæozoic fossils of New South Wales. During the year the Society held eight meetings, at which the following papers were read:—Presidential Address, by H. C. Russell, B.A., F.R.A.S.—Notes on flying-machines, by L. Hargrave.—On a system of accurate measurement by means of long steel ribands, by G. H. Knibbs.—Local variations and vibrations of the earth's surface, by H. C. Russell, B.A., F.R.A.S.—Some causes of the decay of the Australian forests, by Rev. P. MacPherson, M.A.—The history of floods in the Hawkesbury River, by J. P. Josephson, A.M.I.C.E.—The Ringal of the North-Western Himalaya, by Dr. Brandis, F.R.S. (communicated by Baron von F. Müller, K.C.M.G., F.R.S.).—Notes on experiments in mounting the *Amphipleura pellucida* in media having a higher refractive index than Canada balsam, by Dr. W. Morris, F.R.M.S.—Notes on the characters of the Adelong Reefs, by S. H. Cox, F.C.S., F.G.S.—Stone implements of the aborigines of Australia and some other countries, by Rev. P. MacPherson, M.A.—On a form of flying-machine, by L. Hargrave.—On a new form of anemometer, by H. C. Russell, B.A., F.R.A.S.—The Medical Section held eight meetings, at which eighteen papers were read, and the Microscopical Section eight, at which three papers were read. The number of donations received was 1420 volumes and pamphlets, and 310*l*. expended in the purchase of books, &c., for the library. The Society has issued the following list of subjects, with the offer of the Society's bronze medal and a prize of 25*l*. for each of the best researches if of sufficient merit:—Series vi. to be sent in not later than May 1, 1887; (No. 20) on the silver ore deposits of New South Wales; (No. 21) origin and mode of occurrence of gold-bearing veins and of the associated minerals; (No. 22) influence of the Australian climate in producing modifications of diseases; (No. 23) on the Infusoria peculiar to Australia. Series vii., to be sent in not later than May 1, 1888: (No 24) anatomy and life-history of the Echidna and Platypus; (No 25) anatomy and life-history of Mollusca peculiar to Australia; (No. 26) the chemical composition of the products from the so-called Kerosene Shale of New South Wales.—The following Officers and Council were elected for the ensuing year:—President: C. Rolleston, C.M.G.; Vice-Presidents: H. C. Russell, B.A., F.R.A.S.; Dr. Leibius, M.A.; Hon. Treasurer: R. Hunt, F.G.S.; Hon. Secs.: Prof. Liversidge, F.R.S.; F. B. Kyngdon, F.R.M.S.; Council: Hon. Dr. C. K. Mackellar, A.M., M.L.C.; C. Moore, F.L.S.; P. R. Pedley, Dr. J. Ashburton Thompson, C. S. Wilkinson, F.G.S.; Dr. H. G. A. Wright.

Paris

Academy of Sciences, July 26.—M. Jurien de la Gravière, President, in the chair.—On the quantitative analysis of ammonia, by M. Th. Schlœsing. The author's process of analysis, based on distillation in presence of magnesia, having been questioned by M. Berthelot and others, he has made some fresh experiments, here described, which fully confirm the accuracy of the results already obtained.—Observations on the oldest sedimentary groups in the north-west of France, by M. Hébert. The region here dealt with is the northern section of Brittany and Normandy, where the most ancient sedimentary rocks are the clay-slates of Saint-Lô and the widely diffused purple conglomerates. The former, which are quite distinct from the mica-schists, gneiss, and other primitive crystalline schists, form the fundamental feature throughout the department of La Manche, stretching far eastwards into Calvados, and westwards into Brittany. They assume almost everywhere a vertical or nearly vertical disposition, and are remarkably homogeneous, being almost totally destitute of any organic remains. The whole system seems to be posterior to the granitic pudding of Granville.—On the meteorological station of l'Aigoual, by M. F. Perrier. Since the beginning of July this station has been in full activity, and has been furnished by M. Houdaille, of Montpellier, with maxima and minima thermometers, a psychrometer, an evaporometer, and a registering hygrometer. In the neighbourhood other instruments have been fitted up, including Tonnelot and Richard barometers, a large pluviometer, and a Campbell heliograph. Regular observations have already begun to be taken on this peak, which stands at an altitude of 1567 metres above sea-level, on the water-parting between the Atlantic and Mediterranean basins. The present temporary erections will soon be replaced by a solid structure, for which a grant of 4800*l*. has been made by the Minister of Agriculture.—Remarks accompanying the presentation of vol. xii. of the "Mémorial du Dépôt de la Guerre," by Col. F. Perrier. The first part of this volume describes the instruments and apparatus employed in the various geodetic operations connected with the new measurement of the meridian of Paris, with an exposition of the methods of observation. In the second are embodied all the observations taken from 1871 to 1884 between Perpignan and Paris by MM. Perrier, Bassot, and Defforges, at seventy-two stations belonging to the meridian of France.—Note on Gen. Meusnier's projected aërostatic machine, by M. Létonné. The album here referred to is a photographic reproduction of an atlas now in the military aërostatic establishment of Chalais (Meudon), and containing sixteen plates of designs relative to a projected aërostatic machine prepared by Gen. Meusnier between the years 1784 and 1789. Eight tables are added, giving the coefficients of resistance of various substances suited for the construction of this machine.—On the pressure that exists in the contracted section of a gaseous current, by M. Hugoniot. This paper is supplementary to that inserted in the *Comptes rendus* of June 28, showing that the results of M. Hirn's experiments on the flow of gases are in harmony with the laws of hydrodynamics and with the formula of Weisbach or Zeuner, which is a direct consequence of those laws. Some objections raised by M. Hirn himself are here disposed of, and the general conclusion confirmed by fresh argument.—On the velocity of light in the sulphuret of carbon, by M. Gouy. The experiments here described have been carried out with a revolving mirror analogous to that of Foucault, and capable of 800 revolutions per second by means of compressed air. The results correspond with those recently obtained by Mr. Michelson (*American Journal of Science*, and NATURE, March 11 and April 22, 1886).—Note on the construction of an absolute electrometer adapted for the measurement of very high potentials, by MM. E. Bichat and R. Blondlot. By an improvement introduced into the construction of their already described electrometer, the authors have produced an instrument possessing absolute sterility and capable of measuring potentials corresponding to explosive distances of 2·5 centimetres. A model of the apparatus has been constructed by M. D. Gaiffe, of Nancy.—On the slow decomposition of the chlorides in their extended dissolutions, by M. G. Foussereau. Further experiments with the chlorides of aluminium and magnesium, with the double chloride of rhodium and sodium, the bichloride of platina and the sesquichloride of gold show that the recently described phenomenon of decomposition probably extends to a numerous class of chlorides.—On the definition of the coefficient of self-induction in an electro-magnetic system, by M. G. Cabanellas.—On the numerical laws of chemical equilibria, by M. H. Le Chatelier. The formula for the numerical law of the chemical equilibrium of a gaseous system,

$$\log p^n p'^{n'} \ldots p''^{-n''} \ldots - \frac{273}{0{\cdot}542}\int \frac{Q}{T^2} dT = \text{const.},$$

announced by the author in the *Comptes rendus* for November 16 and December 28, 1885, is here established by rigorous demonstration.—Fresh experiments on the decomposition of hydrofluoric acid by an electric current, by M. H. Moissan. These experiments show conclusively that the gas separated by electro

lysis from anhydrous hydrofluoric acid or from the hydrofluorate of fluoride is fluor, as already anticipated.—On the separation of antimony from tin, by M. Ad. Carnot. This difficult process has been successfully accomplished by a method analogous to that already employed by the author for the separation of zinc and cadmium. It is based on the simultaneous employment of oxalic acid and of the hyposulphide of soda.—On the manganites of soda, by M. G. Rousseau.—On the determination of the absolute acidity of the fluids present in the organism, and on some phenomena connected with the saturation of orthophosphoric acid, by M. Ch. Blarez. From the experiments here described it is inferred that the exact determination of the absolute basic property of phosphoric acid is impossible, there being nothing absolute in this property itself; also that it is impossible to determine the absolute acidity of the animal fluids, of whose constituent principles phosphoric acid and the phosphates form part.—On some thermic data relating to the chromates, by M. Paul Sabatier.—Thermic researches on the seleniures, by M. Charles Fabre. The author here deals with the heat of formation of the seleniure of dissolved ammonium, and with some problems connected with the seleniures of lithium.—Researches on some crystallised basic sulphates, by M. Athanasesco. By employing the process used by Friedel for the artificial reproduction of brochantite, the author has succeeded in obtaining fine crystallised subsulphates of cadmium, zinc, alumina, iron, and uranium. By a slightly modified process he afterwards obtained some subsulphates of nickel, cobalt, mercury, and bismuth.—Researches on some crystallised arseniates, by M. Coloriano All these arseniates, except the bibasic, are insoluble in water, and resist the acids. They were obtained by the various processes of Debray, Friedel and Sarasin, Verneuil and Bourgeois.—On a nitrated camphor and its saline and alcoholic combinations, by M. P. Cazeneuve.—Discussion on the reactions of pilocarpine, by MM. E. Hardy and G. Calmels.—Physiological function of the pulmonary tissue in the exhalation of carbonic acid, by M. L. Garnier.—On a universal chromatometer, by M. L. Andrieu (de l'Etang). The apparatus here described and illustrated is intended to define and measure the colours of liquids by giving them numerical expression.—On the Anguillules of smut, by M. G. Pennetier. From his recent experiments the author concludes that these parasites preserve the vital spark for a period of fourteen years, but no longer.—On the milky secretion of pigeons during incubation, by MM. Charbonnel-Salle and Phisalix.—Researches on the structure of the brain of the Myriapods, by M. G. Saint-Remy.—Researches on the Miocene vegetation of Brittany, by M. Louis Crié.—On the picturesque group of rocks collectively known by the name of Montpellier-le-Vieux (Aveyron), by M. E. A. Martel.

BERLIN

Physiological Society, July 2.—Dr. Joseph reported on the results of experiments instituted with a view to ascertaining the influence of the nerves on the skin. Following up the experiments of Waller, he had excised a somewhat large piece of the second cervical nerve peripherically from the ganglion, and a few days thereafter had observed behind the ear of the side operated upon a perfectly circumscribed place on which the hairs had fallen out, but which, beyond the baldness, showed no symptom of change. The cutting through of the posterior root of the cervical nerve had not the same effect, but the extirpation of the second cervical ganglion had that result. The microscopical examination of the hairless spots showed absence of hair papillæ and of the hair root, while the other constituents of the skin remained unchanged. No abnormal vascularisation of the spots in question nor of the ears generally was observed. Seeing that the protected situation of the depillated spot and the presence of sensibility went to disprove the idea of a mechanical removal of the hairs, while the result of the anatomical examination attested that the hairs were exclusively affected without the vascular system having undergone any essential alteration; the speaker was therefore of opinion that the results of his investigations might be taken as demonstration of the existence of trophical nerves. After the separation of the peripherical nerve no change in the ganglion was ever observed, whereas the dissection of the posterior root gave rise to atrophy.—Dr. H. Virchow next demonstrated four drawings representing the incurvations of the vertebrate columns of different human types and manifesting the surprisingly great differences obtaining among the normal vertebrate columns of a Russian, an Italian, a male German existing in model, and a pregnant German wife. From these figures it was to be concluded that the breadth of the normal fluctuations of these incurvations was great. On the study of the vertebral column it was to be observed that it was indeed comparable to an elastic rod which became expanded by lateral pressure, and compressed by pressure from the top, but that it was composed of several parts independent of one another (the lumbar, pectoral, and cervical parts) which were adapted to the special functions of the respective sections of the rump. By a simple model he made these differences among the different sections apparent. On a second model he showed that very marked displacements in the centre of gravity at the uppermost part of the body were equalised, not by compensatory incurvations, but by bendings in the undermost joints. The speaker then demonstrated by curves rendered in paste the incurvations shown by the vertebral column of dead bodies when the ligaments of the vertebrate bodies in front or behind, in the dorsal or lumbar vertebræ, were cut through. The curves became more marked after the elastic ligaments of the upper vertebræ were cut through, but they hardly changed at all when the lowest tendinous ligaments were cut through. The intesticular ligaments consisted of a soft elastic kernel and of distended ligamentous fibres compressing the kernel. The action of the expending kernels, which made the vertebral column firmer, was illustrated by a third model. The speaker had taken exact measure of the situation of the kernel in each disk on vertebrate columns sawn through, and when he combined together these points on a drawing, he obtained a more marked incurvation than that possessed by the vertebral column. Thus altogether apart from the muscular activity, the different forces acted on the incurvation of the vertebrate column, which for the rest appeared to be different in the different races.

BOOKS AND PAMPHLETS RECEIVED

"Indigenous Fodder Grasses of North-West India" (Roorkee).—"Die Ergebnisse der Untersuchungsfahrten, S. M. Knbt." "Drache" (Mittler und Sohn, Berlin).—"Russland," by Von Waldeck (Freytag).—"Der Ozean," by Dr. O. Krümmell (Freytag).—"Die Schweiz," by Dr. Z. Z. Egli (Freytag).—"Vital Statistics of the City of Glasgow," by Dr. J. B. Russell (Macdougall).—"Beiträge zur Biologie der Pflanzen," Vierter Band, Zweiter Heft (Kern, Breslau).—"Transactions of Vasser Brothers' Institute and its Scientific Section," vol. iii. part 1.—"Partiality in Unity" (Wyman).—"Bulletin of the U.S. Geological Survey," Nos. 24, 25, 26 (Washington).—"Speculations from Political Economy," by C. B. Clarke (Macmillan).—"Annalen der k. k. Universitäts Sternwarte in Wien," ii. iii. Band, 1883, by E. Weiss (Wien).—"Report on the Migration of Birds," 7th Report, 1885 (Macfarlane and Erskine).

CENTRAL AMERICAN ENTOMOLOGY

Biologia Centrali-Americana. Insecta: Coleoptera. Vol. III. Part 2, "Malacodermata," by the Rev. Henry Stephen Gorham, F.Z.S., &c. (1880–86.) Vol. V. "Longicornia," by Henry Walter Bates, F.R.S. "Bruchides," by David Sharp, M.B. (London: R. H. Porter, 1879–86.)

TWO more instalments of the entomological portion of this great work show how earnestly it is being pushed on; and if it can be completed on the same lavish scale of illustration, and with the same thoroughness of execution, it will afford materials for a true conception of the richness of insect life in the tropical regions far beyond anything that has been hitherto attempted. Not only will it be superior to any other work of a similar character, but it will probably surpass in magnitude all the other works dealing with tropical insect-faunas combined.

The plan and method of treatment being exactly the same as that of Mr. Bates's volume on the Cicindelidæ and Carabidæ, already reviewed in NATURE (vol. xxxiii. p. 77), it will only be needful here to make a few remarks on points of general interest. Taking first the Malacodermata—a group represented in Britain by our Telephori, "soldiers and sailors," our glow-worm, and other allied forms—Mr. Gorham informs us that nearly one fourth of all the known species of the world are here described from Central America, a preponderance in this district which is due no doubt to the fact that the group has never been a favourite one among coleopterists, and has thus been comparatively little attended to by collectors in the tropics. The large number of 813 species here enumerated as against 1272 of the favourite Longicornes, shows that it is not impossible that this tribe may one day rank among the richest groups of beetles. From a comparison of certain of the best known families in different parts of the world Mr. Gorham is of opinion that the total number of species in the tribe is not less than 12,000. He also states that the tropical American forms are as a whole very distinct from those of Africa and the Eastern tropics, and that they rank as "persistent forms of an earlier stage of development." This is specially interesting, because it agrees so well with the fact that nowhere else in the world do low forms of mammalia and birds constitute so large a proportion of a wonderfully rich fauna as in tropical America. Another suggestive remark is, that whenever "a genus is common to Central or South America and other distant parts of the world, it is also the case that it is represented by a species also identical or nearly so in both districts." Many examples are given of this interesting fact, and the no doubt correct solution is suggested, that in these cases there must have been a comparatively recent transmissal, either from one country to another, or from some common centre to both. The Miocene beetles of Switzerland exhibit so close a resemblance to living forms that we may well suppose these identical species to have been common to Europe and North America in Miocene times, and to have passed southward to the Old and New World tropics respectively when the temperate zones became unsuitable to them.

Of Longicornia about 9000 species are known, so that those from Central America alone are nearly one-seventh of the whole; but in this tribe more perhaps than any other is our knowledge imperfect, owing to the bulk of the species being restricted to the virgin forests, where they are very local and marvellously specialised; while though exceedingly abundant under favourable conditions —that is, when extensive clearances in the forest have been *recently* made—yet at other times they are so scarce that it is impossible to obtain even a moderate collection of them.

Mr. Bates remarks on the wonderful "endemicity" of the tropical American Longicorn fauna, 304 genera out of 330 being exclusively American; while both he and Mr. Gorham insist on the whole of the Central American fauna, including that of the highlands of Mexico, having tropical rather than north-temperate affinities. As regards the Malacodermata, however, the northern parts of Mexico are said to be "totally unexplored," while Mr. Bates states that there are 30 northern generic forms which reach Mexico but rarely go further south.

The Bruchides form a small tribe of usually minute beetles which have been so imperfectly collected in the tropics that no comparisons of any value can be made. No less than 150 species are here enumerated, forming nearly one-fourth of all that are yet known, and nearly 120 of these are new species, 25 of which are figured.

On looking over the beautifully executed coloured plates, on which nearly 500 new species of Longicornes are figured, we are struck by the great preponderance of protective tints in these insects, whole plates being filled with species of delicately mottled brown or grey colours evidently harmonising with the varying hues and rugosities of the tree trunks on which they rest; while those of more elegant forms and brilliant tints are usually of smaller size, except when they gain protection by their resemblance to other inedible insects. It fortunately happens that the other group treated in these volumes—the Malacodermata—are very largely, if not wholly, such a protected group, it having been found by experiment that birds will not eat our gay-coloured Telephori, and Mr. Belt found the same to be the case with the fire-flies of Nicaragua and their allies. In all parts of the world these insects are mimicked by others which have no such protection, and it is interesting to compare the plates in these two volumes and to see how many of the Longicornes have taken on the form and colouring of the Malacoderms. Whenever I noticed a pair which undoubtedly resembled each other, I turned to the descriptions, and in every case found that they inhabited the very same locality. Thus the Longicorn *Otheotethus melanurus* imitates the Malacoderm *Lucidota discolor*, both found at Chontales, the species mimicked having however, as is usual, a wider range. *Tethlimmena aliena* and *Lygistopterus amabilis*, another mimicking pair, are both recorded from Chontales only. *Callia albicornis*, from Panama, resembles two species of Malacoderms, *Silis chalybeipennis* and *Colyphus signaticollis*, both from Panama, and both taken on the Volcano de Chiriqui. If these last two are both inedible, it is a case among the Coleoptera similar to the numerous interesting cases of protected genera of Heliconoid butterflies resembling

each other, the theory of which has been so lucidly explained by Dr. Fritz Müller (see NATURE, vol. xxvi. p. 87, and vol. xxvii. p. 481). A genus of Longicornes has been named *Lycidola*, and its eight known species are all said to resemble species of *Lycus*. Besides these there are at least a score of Longicornes which are evidently mimickers, though the exact species imitated does not happen to be represented on the plates. There are also many of the smaller species which evidently mimic ants or wingless Mutillidæ. Three such species are named by Mr. Belt, and two of these are figured, but they do not appear to resemble ants half so much as at least a score of other species; showing how difficult it is to determine whether a species is protectively coloured by means of figures however carefully drawn and coloured. The extensive collections on which these volumes are founded would, I feel sure, afford a mass of interesting cases of mimicry if search were made for them, since, besides those already mentioned, there seems to be a considerable number of Longicornes which resemble some of the Cleridæ figured among the Malacodermata, and these also are probably cases of mimicry, although I am not aware that the Cleridæ have been proved to be an uneatable group.

Looking at the copious series of figures here given there does not seem to be any superiority of colouring over the corresponding Eastern groups. The much larger proportion of Cerambycidæ to Lamiidæ in tropical America gives it an advantage over the Eastern tropics, because the former family comprises most of the elegant forms and gay colours of the tribe; but notwithstanding their inferiority in this respect the Longicornes of Penang, of Java, and of New Guinea appear to be quite equal in their development of colour to those of Central America.

The present work has been got up at so great an expense both of time, labour, and money to its originators, Messrs. Godman and Salvin, that it must be considered one of the noblest individual contributions to the study of natural history that has ever been made. Its great bulk and cost must, however, render it inaccessible to many students who would wish to possess it, while its value to them would have been considerably increased if descriptions of all the recorded species had been given as well as of those which are new, rendering it a complete book of reference to the Insecta of Central America.

I would therefore suggest to Messrs. Godman and Salvin that they would confer a still greater boon on entomological students if they could make arrangements for the preparation of a series of compact octavo volumes giving the letterpress only of the present work, together with either the original descriptions or sufficient diagnoses of all the species enumerated which are not here described. These volumes could be issued after the completion of the great work, all brought up to one uniform date; and if published at a moderate price they would be sure to command a very large sale. Complete faunal hand-books of the kind suggested are among the most generally useful works that can be published, because they obviate the enormous waste of time and labour involved in consulting scores of expensive volumes in order to determine the name and history of perhaps half the insects which a student may possess.

It is quite unsafe to venture on any detailed criticism of the work of one so thoroughly acquainted with Longicorn Coleoptera as Mr. Bates, but my attention was attracted to Table II. by the figures of two alleged female Prionidæ, which are represented of a rich green colour, while the respective males are bronzy olive. If this is the fact, it is a curious case of reversed sexual coloration, though by no means unprecedented. In one of these species, *Mallaspi belti*, however, two varieties are figured, one green, the other olive brown, both said to be females; but the green specimen (as figured) differs greatly from the brown specimen, in having the femora of the second pair of legs much longer and more slender, in the somewhat different dentation of the thorax, and especially in the very different form of the scutellum, important differences which seem inconsistent with identity of species. Should any error have crept into the plates, the author will no doubt be glad to have his attention called to it.

ALFRED R. WALLACE

GEOMETRICAL OPTICS

An Elementary Treatise on Geometrical Optics. By W. Steadman Aldis, M.A. (London: Deighton, Bell, and Co., 1886.)

THIS is a second edition of a work which appeared first in 1872, and which was designed to meet the requirements of students reading for the first three days of the Mathematical Tripos. The new edition does not differ greatly from the old, except in form. The type is larger and clearer, and in this respect the book is considerably improved.

The laws of reflection and refraction, and the reflection and refraction of direct pencils at plane and spherical surfaces, are treated in a clear and comprehensive manner. In Article 36 reference is made to a useful method of illustrating from co-ordinate geometry the relations between a point and its image. If ϕ, ϕ' be the principal focal lengths of an optical system, u and u' the distances of an object and its image from the principal points, we have $\frac{\phi}{u} + \frac{\phi'}{u'} = 1$. Thus taking rectangular axes, and measuring along them distances ϕ and ϕ', we see that u and u' are the intercepts on the axes made by a straight line passing through the point ϕ, ϕ'. This has been worked out in an interesting paper in the *Philosophical Magazine* for December 1884, by Prof. J. Loudon, of Toronto.

The next chapter deals with the oblique reflection and refraction of small pencils. The general explanation is extremely lucid, but it surely is a mistake not to have introduced the notation of the differential calculus. Of course this is excluded from the first three days of the Tripos, but so too are oblique reflection and refraction, and the work is rendered unnecessarily cumbersome by the omission. A similar remark may apply to some of the sections of the next chapter on refraction through prisms and plates.

Chapter VI. treats of lenses, which are dealt with in the ordinary manner. This part of the book would have been improved by the introduction of some of the geometrical results in which the main consequences of Gauss's work have been expressed by various writers. It is really a misfortune that the theory of principal and nodal points is so little known to English authors. It is

clearly explained in Mr. Pendlebury's book on lenses, but that does not include other parts of the subject, and is somewhat needlessly long.

The book concludes with an account of some simple optical instruments, dispersion and achromatism, and the geometrical theory of the rainbow.

OUR BOOK SHELF

New Commercial Plants and Drugs. By T. Christy, F.L.S., &c. No. 9. (London: Christy and Co., 1886.)

THIS pamphlet of 73 pages treats for the most part of medicinal products, though some consideration is also given to fodder and food-plants, essential oils, india-rubber, and various others. The first article is devoted to the Doundake (*Sarcocephalus esculentus*), a West African Rubiaceous plant, which has attracted some attention of late in cases of nervous paralysis. The root has been analysed by Messrs. Heckel and Schlagdenhauffen, and their analysis is given together with a reproduction of the two plates which accompanied their paper. Two new perfume oils come under consideration, namely, from *Eucalyptus staigeriana* and *Backhousia citriodora*. The first is a Queensland tree, and is known as the lemon-scented iron bark. The odour of the leaves is said to be exactly like that of the lemon-scented verbena, and the oil yielded by them is identical in fragrance with that from *Andropogon citratus*, or lemon-grass oil, which is imported into this country both from Ceylon and Singapore, where the plants are very extensively cultivated. Mr. Christy says that "the odour of the oil of this tree is quite different from that of *Eucalyptus citriodora*, which resembles, and might be substituted for, citronella oil, so extensively used for perfuming soap." The *Backhousia* oil is described as being like that of *Eucalyptus staigeriana*, and upon being tested for scenting soaps it was found to answer well, and would probably find a ready market in this country if it could be imported at a price to compete with ordinary verbena oil. It might realise 1*s*. 4*d*. to 2*s*. per pound.

The Kava root (*Piper methysticum*) of the Fiji Islands, which is so well known for the disgusting ceremonies which, in former times perhaps more than the present, accompanied its preparation, has of late years been introduced amongst us for its medicinal properties. The active principle of the Kava root appears to reside in a resinous substance extracted with alcohol. From a series of experiments it seems that this principle is a substance of very great importance as a local anæsthetic, but that in larger doses it produces a scaly affection of the skin. From the Kava root a spirit or liqueur has been distilled, and this under the name of Yagona is on sale at the refreshment bars of the present Colonial and Indian Exhibition.

Another new drug which probably has a future before it is the Kombe of Central Africa (*Strophanthus hispida* or *S. Kombe*) which has been proved to be of considerable value in affections of the heart. The first communication relating to the physiological action of this drug was made by Prof. Fraser to the Royal Society of Edinburgh in 1870, which was followed in 1885 by a more elaborate paper at the Cardiff Meeting of the British Medical Association. There seems, however, even after this lapse of time to be a difficulty in obtaining the seeds in quantity, or even the right species, several forms having been introduced from the Gold Coast, Sierra Leone, and other parts of Africa; the chief difference lies in the seed, some forms of which are covered with long, fine silky hairs.

Mr. Christy's pamphlet, like its predecessors, is a useful record of newly introduced and useful plants.

Heidelberg gefeirt von Dichtern und Denkern seit fünf Jahrhundesten. Herausgegeben von Albert Mays. (Heidelberg, 1886.)

IT was a happy thought of the compiler of this volume to collect and publish on the five hundredth anniversary of the foundation of the University of Heidelberg a selection of what has been written about the city and the University by eminent men of various nations at different periods of time. A collection of all that has been written about the ancient city and its lovely situation would, Herr Mays says, fill a respectable library, for besides histories in verse of the Palatinate and its capital there are innumerable tales, novels, and the like based on incidents in its history, and lyrical and historical poems on Heidelberg by the hundred. In making a selection from this vast mass of matter, the compiler has only retained poems or descriptions which are of special poetical or literary value, or those which are of special interest on account of the author, or, finally, those which exhibit some special originality or peculiarity. But even when thus winnowed a handy volume is left. Needless to say, the vast majority of the writers are German; there are a few English, and one American (Longfellow) The list commences with an extract from the Bull of Pope Urban VI. of October 23, 1385, authorising Prince Rupert to found the University. This is followed by extracts from over sixty authors arranged chronologically. Herr Mays notices as a curiosity that not one of these is French. The English authors naturally dwell on the castle, "next to the Alhambra of Granada the most magnificent ruin of the Middle Ages," rather more than on the University; but indeed the German writers do the same. The book will show the good people of Heidelberg, if they lack such knowledge at this festive season, that they are citizens of no mean city. It should also prove an interesting memento to many in Europe and America who have passed a few years at the most impressionable period of their lives at the old University, which, with its sister at Bonn, has of late years drawn the British student away from Göttingen.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Organic Evolution

FOR some time I have much desired to direct the attention of your readers all over the world to the two very remarkable articles on Organic Evolution, by Mr. Herbert Spencer, which appeared in the April and May numbers of the *Nineteenth Century*. I hope they will be separately published. They mark in my opinion a new departure in the Philosophy which has been built up by a certain school of writers on the Darwinian Theory. Let me explain what I mean.

From the first discussions which arose on this subject I have ventured to maintain that the successors of Darwin have run quite wild from the teaching of their master—that his Hypothesis, even if completely true so far as it went, offered no adequate explanation whatever of the multiform and complicated facts of Organic Evolution—that the phrase "natural selection" represented no true physical cause, still less the complete set of causes requisite to account for the orderly procession of organic forms in Nature; that in so far as it assumed variations to arise by accident it was not only essentially faulty and incomplete, but fundamentally erroneous; in short, that its only value lay in the convenience with which it groups under one form of words, highly charged with metaphor, an immense variety of causes, some purely mental, some purely vital, and others purely physical or mechanical.

The violence with which false interpretations were put upon this Theory and a function was assigned to it which it could never fulfil, will some day be recognised as one of the least creditable episodes in the history of science. With a curious perversity it was the weakest elements in the Theory which were seized upon as the most valuable, particularly the part assigned to blind chance in the occurrence of variations. This was valued not for its scientific truth,—for it could pretend to none,—but because of its assumed bearing upon another field of thought and the weapon it afforded for expelling Mind from among the causes of Evolution.

There have been many symptoms that this Philosophy is breaking down. Mr. Herbert Spencer, although he has worked out the consequences of Evolution with enthusiasm, has never been blind to some of its defects. His mind is too closely analytical not to be brought into contact at many points, with its manifest inapplicability and its wordy hollowness.

But in these two articles we have for the first time an avowed and definite declaration against some of the leading ideas on which the Mechanical Philosophy depends; and yet the caution, and almost the timidity, with which a man so eminent approaches the announcement of conclusions of the most self-evident truth—is a most curious proof of the Reign of Terror which had come to be established.

I cannot in this letter indicate the breadth and sweep of the admissions now made by Mr. Herbert Spencer in the two articles referred to,—fatal to the adequacy of the Mechanical Philosophy as any explanation of organic evolution. They cluster round, and follow from the central admission that "the words 'natural selection' do not express a cause in the physical sense." Another great admission is that the "co-operation" which is required in the growth and development of useful parts, cannot be accidental.

Of course, now that so eminent a man as Mr. Herbert Spencer has opened his eyes and his mouth to these—and many other—admissions, we shall have all the *Dii Minores* following suit.

I have read with great pleasure an article in your last number (p. 314) on "Physiological Selection," with an "additional suggestion on the origin of species." I rejoice that the author has at last discovered that "natural selection has been made to pose as a theory of the origin of species, whereas in point of fact it is nothing of the kind." This has been my contention for many years. ARGYLL

Aurora

WITH reference to the aurora of July 27, accounts of which appear in NATURE, vol. xxxiv. pp. 311 and 312, the following particulars of the accompanying magnetic disturbance recorded here may be of interest. The disturbance commenced about 3 p.m. on July 27 with small fluctuations in declination and horizontal force, followed by larger movements which commenced sharply at 10.20 p.m. in all three elements, and continued to about 7 a.m. on July 28. The greatest movement was between 10.20 and 11.30 p.m., amounting to 45′ in declination, ·011 of the horizontal force, and ·005 of the vertical force. Corresponding earth-currents were recorded as usual.

Royal Observatory, Greenwich, August 10

Mock Suns

KINDLY add the following, to make up for omission of my figure in your issue of July 29 (p. 289):—

The "arched eyebrows," as I called them, can best be described thus—

Resting on the top of the halo circle, where the third mock light stood, was a bow of peculiar curve. It was like two well-arched eyebrows flowing together by a curve of gentle dip at the point where it touched the halo. Each arch was about equal to one-eighth part of the halo circle in every respect except that its centre lay about the middle of the chord joining the upper mock light with the mock light on that side of the sun. The contrariflexure, and the anomalous positions of the two centres of the two arches, strike me as very noteworthy. I cannot presume to guess at an explanation.

May I add that a correspondent of the *Standard* states that he too saw the white ray on the *left* side; and that it stretched, to use his expression, "round the sky almost to the east, and at the end of it was another mock sun much less brilliant," where it "seemed about to begin a fresh series of mock suns and circles." This too seems to me too striking a feature to be lost to record in NATURE. W. J. HERSCHEL

Littlemore, August 2

Meteors

ON August 4, 10h. 40m., a beautiful slow meteor was seen here threading its way from about 2° S. of *o* Ursæ Majoris to very slightly below β Aurigæ. Its light fluctuated greatly, but at its best it must have been brighter than Jupiter, though the effect was much marred by mist. The most noteworthy feature was its extreme slowness of movement; a careful determination gave 8 seconds as the time it remained in sight. There was no train of any sort; the meteor rolled along with a star-like aspect, and its velocity near the end point became so much impeded that it seemed almost stationary. I observed fifty-seven other meteors during the same night, but none of these could be associated in appearance and direction with the one specially described. Its radiant-point was probably in Ursa Major, close to β, at about $162° + 59°$.

On August 6, 10h. 3m., a meteor equal to Jupiter was seen pursuing a long path just south of and nearly parallel to α and ϵ Pegasi. It left a bright streak, and was a conspicuous object, notwithstanding the moonlight. The radiant-point was at about $32° + 17°$, nearly 6° S.S.E. of α Arietis, or possibly in the extreme east boundaries of Aries.

It would be important to hear of duplicate observations of these large meteors. In the eastern parts of England they must have appeared very bright, and being visible at a convenient hour in the evening many persons will have noticed them.

Bristol, August 9 W. F. DENNING

LAST night at about eleven o'clock a fine meteor was visible here through an opening in clouds. Its path was in Aquarius, commenced a little to the east of η, and seemed to be in the direction of a line joining η and δ. In three or four seconds the meteor passed over about 20°, and it left momentarily a trail over the last 10°. This was slightly curved, the convex side being to the east, and the colour varying from yellow for a quarter of the curve to red during the remainder. At first the meteor resembled Saturn in size and colour, then became larger, whiter, and afterwards pale blue, and when it finally disappeared behind the clouds it considerably exceeded Venus at her brightest, both in size and brilliance. Ramsey, Isle of Man, August 5

PHYSIOLOGICAL SELECTION: AN ADDITIONAL SUGGESTION ON THE ORIGIN OF SPECIES [1]

II.

NEXT, let it be observed that we cannot expect to meet with much direct evidence of physiological selection from our domesticated varieties. For, first, breeders and horticulturists keep their strains separate artificially, and preserve many kinds of variation other than those of the reproductive system with which alone we are concerned; and, secondly, it is never the aim of these men to preserve this particular kind of variation. Therefore, all that we can here learn from our domesticated productions is the paramount importance of preventing intercrossing with parent forms, if a new varietal form is ever to gain a footing. No one of these domesticated varieties could have been what it now is unless such intercrossing had been systematically prevented by man; and this gives us good reason to infer that no natural species could have been what it now is unless every variety in which every species originated had been prevented from intercrossing with its parent form by nature. For the cases are extremely rare in which one species differs from another (living or extinct) in respect of any feature so highly utilitarian in character as to justify belief that the newer species owed its differentiation to natural selection having been able to overcome the swamping effects of free intercrossing.

[1] Abstract of a Paper read before the Linnean Society on May 6, by George J. Romanes, M.A., LL.D., F.R.S. &c. Continued from p. 316.

Again, as to plants and animals in a state of nature, the particular variation with which we are concerned would scarcely be noticed until it had given rise to a new species. In this respect, therefore, the theory of physiological selection is in the same predicament as that of natural selection: in neither case are we able directly to observe the formation of one species out of another by the agency supposed; and, therefore, in both cases our belief in the agency supposed must to a large extent depend on the probability established by general considerations. Nevertheless, although our sources of direct evidence are thus seen to be necessarily limited, I shall now hope to show that they are sufficient to prove the only fact which they are required to prove—namely, that the particular kind of variation, on the occurrence of which my theory depends, does occur both in nature and under domestication.

One very obvious example of the particular variation which is required by the theory of physiological selection has already been given in the season of flowering or of pairing being either advanced or retarded. This I take to be a most important case for us, inasmuch as it is one that must frequently arise in nature. Depending as it chiefly does on external causes, numberless species both of plants and animals must, I believe, have been segregated by its influence. For in every case where a change of food, temperature, humidity, altitude, or of any of the other many and complex conditions which go to constitute environment—whether the change be due to migration of the species or to alterations going on in an area occupied by a stationary species—in every case where such a change either retards or promotes the season of propagation, there we have the kind of variation which is required for physiological selection. And it is needless to give detailed instances of such variation where this is due to so well known and so frequently observed a cause.

But it is on what may be called the spontaneous variability of the reproductive system itself that I mainly rely for evidence of physiological selection. The causes of variability are here much more numerous, subtle, and complex than are such extrinsic causes as those just mentioned; and they are always at work in the reproductive systems of all organisms. The consequence is, as Mr. Darwin has shown by abundant evidence, that variations in the direction of sterility depend more on what he calls the nature of the organism than on the influence of external conditions. Of this fact we have direct evidence, firstly in individuals, secondly in varieties, and thirdly in species.

(1) *Individuals.*—Mr. Darwin observes, "it is by no means rare to find certain males and females which will not breed together, though both are known to be perfectly fertile with other males and females. We have no reason to suppose that this is caused by these animals having been subjected to any change in their habits of life; therefore such cases are hardly related to our present subject. The cause apparently lies in an innate sexual incompatibility of the pair when matched." He then proceeds to give examples from horses, cattle, pigs, dogs, and pigeons, concluding with the remark that "these facts are worth recording, as they show, like so many previous facts, on what slight constitutional differences the fertility of an animal often depends." Elsewhere he gives references to similar facts in the case of plants; and instances of this individual incompatibility, both in plants and animals, might easily be multiplied.

Now, if even as between two individuals there may thus arise absolute sterility without there being in either of them the least impairment of fertility towards other individuals, much more may such incompatibility extend towards a number of individuals. For certainly the most remarkable feature about this individual incompatibility is the fact of its being only individual: it would not be nearly so remarkable, or antecedently improbable, if the incompatibility were to run through a whole race or strain. In the fact of individual incompatibility, therefore, we have the kind of variation which my theory requires, and this as arising spontaneously in the highest degree of efficiency.

(2) *Races.*—But of even more importance for us is the direct evidence of such a state of matters in the case of varieties, breeds, or strains. In the ninth chapter of the "Origin of Species," and in the nineteenth chapter of the "Variation of Plants and Animals under Domestication," Mr. Darwin adduces miscellaneous instances of varieties of the same species which exhibit a higher degree of fertility within themselves than they do with one another. In this respect, therefore, they resemble natural species; but as they are only domesticated varieties known to belong to the same species, they are here available as evidence of what may be termed racial incompatibility, or of the particular kind of variation which my theory requires. To quote only two instances: "The yellow and white varieties (of Verbascum) when crossed produce less seed than the similarly coloured varieties"; and the blue and red varieties of the pimpernel are absolutely sterile together, while each is perfectly fertile within itself. Such instances are the more suggestive on account of their arising under domestication, because, as a rule, domestication increases fertility, and is thus inimical to sterility—sometimes even breaking down the physiological barriers between natural species. Therefore, if in some cases even under domestication the reproductive system may vary in this manner, so as to erect physiological barriers between artificial varieties, much more are such barriers likely to be erected between varieties when these arise in a state of nature.

But as regards varieties in a state of nature, I have not been able to meet with any evidence of racial incompatibility. Nor is this to be wondered at: for, unless the degree of such incompatibility were well pronounced, it would not be noticed; while, if it were well pronounced, the two varieties would for this very reason be classified as species. Therefore, the fact of racial incompatibility within the limits of wild species could only be proved by experiments undertaken expressly for the purpose, in the way which I shall afterwards explain.

(3) *Species.*—According to the general theory of evolution, which in this paper is taken for granted, the distinction between varieties and species is only a distinction of degree; and the distinction is mainly, as well as most generally, that of mutual sterility. Therefore my theory of physiological selection is here furnished with an incalculable number of instances of the particular kind of variation which is required; for in so many instances as variation has led to any degree of sterility between parent and varietal forms—or between the varying descendants of the same form—in so many instances it is merely a statement of fact to say that physiological selection must have taken place. There remains, however, the question whether the particular change in the reproductive system which led to all these cases of mutual sterility was anterior or posterior to changes in other parts of the organism. For, if it was anterior, these other changes—even though they be adaptive changes—were presumably due to the sexual change having interposed its barrier to crossing with parent forms; while, if the sexual change were posterior to the others, the presumption would be that it was the latter which, by their reaction on the sexual system, induced the former. I shall have to consider this alternative later on. Here, therefore, it is enough to point out that under either possibility the principles of physiological selection must have been at work; only these principles are accredited with so much the more causal influence in the production of species in the proportion that we find reason to suppose the sexual change to have been, as a rule, the prior change. But under either alternative, and on the doctrine that species are extreme

varieties, we have many hundreds of thousands of instances of fertility within the varietal forms with sterility towards allied forms.

Probably enough has now been said to show that, as a matter of fact, the particular kind of variation in the reproductive system which is required by the theory of physiological selection does occur, firstly, in individuals; secondly, in races; and thirdly, in species. But the evidence of physiological selection as an agency in the evolution of species is so far only *primâ facie*. That is to say, although we have evidence to prove the occurrence of this particular kind of variation, and although we can see that whenever it does occur it must be preserved, as yet we have seen no evidence to show how far this kind of variation has been at work in the formation of species. I will, therefore, next proceed to give an outline sketch of the evidence which I have been able to find, tending to show that the facts of organic nature are such as they ought to be, if it is true that physiological selection has played any considerable part in their causation. And to do this I will begin by taking the three cardinal objections to the theory of natural selection with which I set out—namely, sterility, intercrossing, and inutility. For, as we shall see—and this in itself is a suggestive consideration—all the facts which here present formidable obstacles to the theory of natural selection, when this is regarded only as a theory of the origin of species, are not only explained by the theory of physiological selection, but furnish to that theory some of the best evidence which I have been able to find.

Argument from Sterility.—In what respects do species differ from one another? They differ firstly, chiefly, and most generally in respect of their reproductive systems: this, therefore, I will call the primary difference. Next, they differ in an endless variety of more or less minute details of structure, which are sometimes adaptive and sometimes not. These, therefore, I will call the secondary differences. Now, the secondary differences are never numerous as between any two allied species: in almost all cases they admit of being represented by units. Yet, if it were possible to enumerate all the specific differences throughout both the vegetable and animal kingdoms, there would be required a row of figures expressive of many millions. In other words, the secondary specific distinctions may occur in any parts of organisms, but never occur in many parts of the same organism. So that, if we have regard to the whole range of species, the secondary distinctions are seen to be, in the highest imaginable degree, variable or inconstant: the only distinction which is at all constant or general is the primary distinction, or the one which belongs exclusively to the reproductive system. Surely, therefore, what we primarily require in any theory of the origin of *species*, is an explanation of this relatively constant or general distinction. But this is just what all previous theories fail to supply. Natural selection accounts for some among the many secondary distinctions, but is confessedly unable to explain the primary distinction. The same remark applies to sexual selection, use and disuse, economy of growth, correlated variability, and so forth. Even the prevention of intercrossing by geographical barriers or by migration is unable to explain the very general occurrence of some degree of sterility between two allied varieties which have diverged sufficiently to take rank as different species. All these theories, therefore, are here in the same predicament: they profess to be theories of the origin of species, and yet none of them is able to explain the one fact which more than any other goes to constitute the distinction between species and species. The consequence is that most evolutionists here fall back upon a great assumption: they say it must be the change of organisation which causes the sterility—it must be the secondary distinctions which determine the primary. But the contrary proposition is surely at least as probable, namely, that it is the sterility which, by preventing intercrossing with parent forms, has determined the secondary distinctions—or, rather, that it has been the original condition to the operation of the modifying causes in all cases where free intercrossing has not been otherwise prevented. For, obviously, it is a pure assumption to say that the secondary differences have always been historically prior to the primary difference, and that they stand to it in the relation of cause to effect. Moreover, the assumption does not stand the test of examination, as I will now proceed to show.

(1) On merely *a priori* grounds it scarcely seems probable that whenever any part of any organism is slightly changed in any way by natural selection, or by any other cause, the reproductive system should forthwith respond to that change by becoming sterile with allied forms. Yet this is really what the assumption in question requires, seeing that *all* parts of organisms are subject to the secondary specific distinctions. What we find in nature is a more or less constant association between the one primary distinction and an endless profusion of secondary distinctions. Now, if this association had been between the primary distinction and some one—or even some few—secondary distinctions, constantly the same in kind; in this case I could have seen that the question would have been an open one as to which was the conditional and which the conditioned. But as the case actually stands, on merely antecedent grounds, it does not appear to me that the question is an open one. Here we have a constant peculiarity of the reproductive system, repeated over and over again—millions of times—throughout organic nature; and we perpetually find that when this peculiar condition of the reproductive system is present, it is associated with structural changes elsewhere, which, however, may affect any part of any organism, and this in any degree. Now, I ask, is it a reasonable view that the one constant peculiarity is always the result, and never the condition, of any among these millions of inconstant and organically minute changes with which it is found associated?

(2). But, quitting *a priori* grounds, it is a matter of notorious fact that in the case of nearly all our innumerable artificial productions, organisms do admit of being profoundly changed in a great variety of ways, without any reaction on the reproductive system following as a consequence.

(3) Again, as regards wild species, Mr. Darwin proves that "the correspondence between systematic affinity and the facility of crossing is by no means strict. A multitude of cases could be given of very closely allied species which will not unite, or only with extreme difficulty; and, on the other hand, of very distinct species which unite with the utmost facility." And he goes on to say that "within the limits of the same family, or even of the same genus, these opposite cases may occur"; so that "the capacity of the species to cross is often completely independent of this systematic affinity, that is, of any difference in their structure or constitution, excepting in their reproductive systems." Now, on the supposition that sterility between species is always, or generally, caused by the indirect influence on the reproductive system of changes taking place in other parts of the organism, these facts are unintelligible—being, indeed, as a mere matter of logic, contradictory of the supposition.

(4) Mr. Darwin further shows that, "independently of the question of fertility, in all other respects there is the closest general resemblance between hybrids and mongrels." Clearly, this fact implies that natural selection and artificial selection run perfectly parallel in all other respects, save in the one respect of reacting on the reproductive system, where, according to the views against which I am arguing, they must be regarded as differing, not only constantly, but also profoundly.

(5) Lastly, Mr. Darwin concedes—or rather insists—

that "the primary cause of the sterility of crossed species is confined to differences in their sexual elements." A general fact which assuredly proves that the primary specific distinction is one with which the organism as a whole is not concerned: it is merely a local variation which is concerned only with the sexual system. Why, then, should we suppose that it differs from a local variation taking place in any other part of the organism? Why should we suppose that, unlike all other such variations, it can never be independent, but must always be superinduced as a secondary result of changes taking place elsewhere? It appears to me that the only reason why evolutionists suppose this is because the particular variation in question happens to have as its result the origination of species; and that, being already committed to a belief in natural selection or other agencies as the causes of such origination, they are led to regard this particular kind of local variation as not independent, but superinduced as a secondary result of these other agencies operating on other parts of the organism. But once let evolutionists clearly perceive that natural selection is concerned with the origin of species only in so far as it is concerned with the origin of adaptive structures—or of some among the secondary distinctions—and they will perceive that the primary specific distinction takes its place beside all other variations as a variation of a local character, which may, indeed, at times be due to the indirect influence of natural selection, use, disuse, and so forth; but which may also be due to any of the numberless and hidden causes that are concerned with variation in general.[1]

I trust, then, that reasons enough have now been given to justify my view that, if we take a broad survey of all the facts bearing on the question, it becomes almost impossible to doubt that the primary specific distinction is, as a general rule, the primordial distinction. I say "as a general rule," because the next point which I wish to present is that it constitutes no part of my argument to deny that in some—and possibly in many—cases the primary distinction may have been superinduced by the secondary distinctions. Indeed, looking to the occasional appearance of partial sterility between our domesticated productions, as well as to the universally high degree of it between genera, and its universally absolute degree between families, orders, and classes, I see the best of reasons to conclude that in *some* cases the sterility between *species* may have been originally caused, *and in a much greater number of cases subsequently intensified*, by changes going on in other parts of the organism. Moreover, I doubt not that of the agencies determining such changes natural selection is probably one of the most important. But what does this amount to? It amounts to nothing more than a re-statement of the theory of physiological selection. It merely suggests hypothetically the cause, or causes, of that particular variation in the reproductive system with which alone the theory of physiological selection is concerned, and which, as a matter of fact, *howsoever caused*, is found to constitute the one cardinal distinction between species and species. Therefore I am really not concerned with what I deem the impossible task of showing how far, or how often, natural selection—or any other cause—may have induced this particular kind of variation in the reproductive system by its operations on other parts of an organism. Even if I were to go the full length that other evolutionists have gone, and regard this primary specific distinction as in all cases due to the secondary specific distinctions, still I should not be vacating my theory of physiological selection: I should merely be limiting the possibilities of variation within the reproductive system in what I now consider a wholly unjustifiable manner. For, as previously stated, it appears to me much the more rational view that the primary specific distinction is likewise, as a rule, the primordial distinction; and that the cases where it has been superinduced by the secondary distinctions are comparatively few in number.[1]

If we thus regard sterility between species as the result of what I have called a local variation, or a variation arising only in the reproductive system—whether this be induced by changes taking place in other parts of the organism, to changes in the conditions of life, or to changes inherent in the reproductive system itself—we can understand why such sterility rarely, though sometimes, occurs in our domesticated productions; why it so generally occurs in some degree between species; and why as between species it occurs in all degrees.

It rarely occurs in our domesticated productions because it has never been the object of breeders or horticulturists to preserve this kind of variation. Yet it sometimes does occur in some degree among our domesticated productions, because the changes produced on other parts of the organism by artificial selection do, in a small percentage of cases, react upon the reproductive system in the way of tending to induce sterility with the parent form, while not lessening fertility with the varietal form. Again, this particular condition of the reproductive system is so generally characteristic of species simply because in as many cases as it occurs it has constituted the reason why species exist as species. And, lastly, this particular variation in the reproductive system has taken place under nature in such a variety of degrees—from absolute sterility between species up to complete, or even to more than complete, fertility—because natural species, while being records of this particular *kind* of variation are likewise the records of all *degrees* of such variation which have proved sufficient to prevent overwhelming intercrossing with parent forms. Sometimes this degree has been less than at other times, because other conditions—climatic, geographical, habitatorial, physiological, and even psychological[2]—have co-operated to prevent intercrossing, with the result of a correspondingly less degree of sterility being required to secure a differentiation of specific type. Lastly, where species have been evolved on different geographical areas, or by use, disuse, and other causes of a similarly "direct" kind, there has been no need to prevent intercrossing in any degree; so that allied species formed under any of these conditions may still remain perfectly fertile, or even more than naturally fertile, with one another.

In view of these considerations, I should regard it as a serious objection to my theory if it could be shown that sterility between allied species is invariably absolute, or even if it could be shown that there are no cases of unimpaired fertility. What my theory would expect to find is exactly what we do find—namely, an enormous majority

[1] Mr. Darwin himself does not appear to have held the view against which I am now arguing—v.z. that the primary distinction is always, or usually, superinduced by the secondary. Not even here, therefore, is his authority opposed to my views: upon this question his voice is merely silent.

[1] The paper here develops another line of argument which it is difficult to render in abstract. Its object, however, is to show that, even in the cases where the primary distinction is superinduced by the secondary—whether these cases are, as I believe, "comparatively few" or comparatively numerous—my theory is available to explain why the primary distinction is so habitual an accompaniment of the secondary distinctions, of whatever kinds or degrees the latter may happen to be. For, according to my theory, the reason of this association in such cases is that it can only be those kinds and degrees of secondary distinction which are able so to react on the reproductive system as to induce the primary distinction that are, *for this reason*, preserved. Or, otherwise expressed, in cases where the secondary distinctions induce the primary, the former owe their existence to the fact that they happened to be of a kind capable of producing this particular effect. Under this view, even in these cases it is the principles of physiological selection that have determined the kinds of secondary distinction which are allowed to survive. For these principles have, in all such cases, *selected* the particular kinds of secondary distinction which have proved themselves capable of so reacting on the reproductive system as to bring about the primary distinction—a general view of the subject which appears to be justified by the very general association between the two.

[2] See "Origin of Species," p. 81, where it is shown that among vertebrated animals different varieties of the same species, even when living on the same area, frequently exhibit a marked repugnance to pairing with one another. In the same passage, it is remarked the different varieties sometimes occupy different stations.

of instances where sterility occurs in all degrees, with a few exceptional instances where secondary distinctions have been able to develop without being associated with the primary distinction. So that, on the whole, I cannot but candidly consider that all the facts relating to the sterility of natural species are just what they ought to be, if they have been in chief part due to the principle which I am advocating. Mr. Darwin appears to have clearly perceived that there must be some one principle serving to explain all these facts—so curiously related, and yet so curiously diverse. For he says, and he says most truly, "We have conclusive evidence that the sterility of species must be due to some principle quite independent of natural selection." I trust I have now said enough to show that, in all probability, this hitherto undetected principle is the principle of physiological selection.

(*To be continued.*)

RED SUNSETS AND VOLCANIC ERUPTIONS

THE great volcanic eruption in New Zealand raises anew the question of the connection between volcanic eruptions and sunset phenomena arising from attenuated matter in the upper regions of the atmosphere. The theory that the noteworthy sunsets about the end of 1883 were due to the Krakatão eruption has been questioned on the ground that, in many parts of the world, these red sunsets have continued until the present time, though not with the same intensity as in 1883. Beautifully variegated sunsets have always been very common in this country. The result was that the sunset phenomena of 1883 did not appear to us as anything new in kind, but only as an intensification of something with which we were already familiar. In order to reach a decisive conclusion we must have observations made in regions where the upper atmosphere is exceptionally free from vapours or other attenuated matter. The advent of such matter can then be detected when it could not be detected at other places. Among such regions I would suggest South Africa, especially the Cape of Good Hope. During my brief residence there in November and December of 1882, nothing was more striking than the extreme whiteness and purity of the western twilight. If such a twilight is there the rule during the whole year, then any diffusion of volcanic vapour in the upper atmosphere must produce a very striking effect. I would therefore suggest to observers in that region the value of precise information on this point, especially with a view of learning to what extent, and within what time, the red sunsets of 1883 disappeared, and whether any such phenomena now reappear as the result of the volcanic eruption in New Zealand. S. NEWCOMB

MR. FORBES'S EXPEDITION TO NEW GUINEA

NATURALISTS will be glad to learn that a collection of natural history objects has been sent to England by our countryman Mr. H. O. Forbes, who has been doing good work on the Astrolabe Mountains in south-eastern New Guinea. Unfortunately a lack of proper support appears to have greatly crippled the efforts of this energetic traveller, who fears that he may be compelled to abandon his proposed expedition to Mount Owen Stanley, the ascent of which was the primary object of his explorations on leaving England. The disaster which befel Mr. Forbes at Batavia, where the boat with all his equipment for the expedition was capsized and everything lost, will be fresh in the recollection of our readers (see NATURE, vol. xxxii. p. 552), and it is only by the utmost display of courage and energy, and by a large pecuniary sacrifice on his own part, that Mr. Forbes has been able to fit out an expedition to New Guinea from Brisbane. It is to be hoped that the great Societies of this country and Australia will not allow this expedition to come to an end for lack of funds. Mr. Forbes has shown what he can do in the cause of science, and a little timely help would now enable him to conduct the work of exploration on which his soul is bent and bring it to a successful issue. It is not generally known in this country that during his last expedition to the Malay Archipelago he expended more than 600*l*. of his own money in endeavouring to render his expedition more complete, and nothing but a little generous encouragement is needed to enable him to sustain the serious pecuniary loss which has befallen him in his attempt to reach Mount Owen Stanley. At the time of writing, we hear that there is a prospect of Australia coming to the rescue and aiding Mr. Forbes towards the attainment of his object, and we trust that England will also do something for a man who, as an explorer and a naturalist, has reflected credit on his country.

The district recently explored by Mr. Forbes has been visited before by Mr. Goldie and Mr. Hunstein, the latter of whom has procured some remarkable novelties among the Birds of Paradise, which have been recently described by Dr. Finsch and Dr. Meyer (*Zeitsch. Ges. Orn.* ii. pp. 369-391). Hunstein has indeed penetrated further than Mr. Forbes was able to do on the present occasion, as the latter has as yet only worked the Sogeri district from a height of 1000 to 5000 feet, and this only in the rainy season.

Among the many interesting species found by Mr. Forbes in the Sogeri district may be mentioned *Harpyopsis novæ-guineæ*, Salvad, *Charmosyna stellæ*, Meyer, *Psittacella pallida*, Meyer (scarcely to be distinguished from *P. brehmi* of Mount Arfak), *P. madaraszi*, Meyer, *Eos incondita*, Meyer, *Parotia lawesi*, Ramsay, *Lophorina minor*, Ramsay, *Paradisornis rudolphi*, Meyer, *Amblyornis subalaris*, Sharpe, *Paradisea raggiana*, Sclater, *Microdynamis parva*, Salvad (*Rhamphomantis rollesi*, Ramsay), *Melidectes emilii*, Meyer, *Rallicula rubra*, Schlegel, and many other notable species, amongst which are two which appear to be undescribed, viz.,

Melirrhophetes batesi, sp. n.

M. similis *M. ochromelani*, Meyer, sed fasciâ supraoculari cervina distinguendus. Long. tot. 9·3, culm. 1·35, alæ 4 8, caudæ 4·2, tarsi 1·15.

Pseudogerygone cinereiceps, sp. n.

P. similis *P. flavilaterali*, Gray, ex Novâ Caledoniâ, sed minor, et rectricibus haud subterminaliter albo fasciatis distinguenda. Long. tot. 3·4, culm. 0·4, alæ 1·9, caudæ 1·2, tarsi 0·65.

It was a little unfortunate for Mr. Forbes that Mr. Hunstein should have visited the Horse-shoe Range so shortly before the arrival of the former in New Guinea, but it says much for the complete way in which Mr. Forbes does his work of exploration, that he should have obtained specimens of nearly every one of the new species discovered by Mr. Hunstein. Unfortunately the Birds of Paradise were out of colour at the time of his visit, but the specimens sent are of great interest, as showing the moults and changes of plumage in these birds. Of the extraordinary species known as Prince Rudolph's Bird of Paradise (*Paradisornis rudolphi*) with blue wings and blue flank-plumes, Mr. Forbes secured only one, apparently a female. As these surprising novelties have been discovered in the Astrolabe Range, which has an elevation of less than 5000 feet, what prizes and discoveries may not be awaiting the explorer if he reaches Mount Owen Stanley with an altitude of 13,000 feet? May he succeed!

R. BOWDLER SHARPE

THE PERSISTENT LOW TEMPERATURE

IT is seldom that the weather maintains such a decided persistency for temperatures below the average conditions. Week after week passes, and the thermometrical

records are monotonously alike in chronicling low temperatures over the whole country.

The Weekly Weather Reports issued by the Meteorological Office are compiled from observations at stations fairly representative of the whole of the British Islands, and the results are grouped into twelve districts. These returns show that the low temperature is not limited to any special area of the United Kingdom, but is common to every part. From the middle of May to the beginning of August there was only one week, ending July 5, in which the temperature was above the average in the western districts of England, Ireland, or the Channel Islands, whilst in the period of seven months from January 4 to August 2 the temperature in the north-west and south-west of England and in the Channel Islands has only been above the average in three weeks—March 29, May 10, and July 5; and averaging the results for the whole of the British Islands, these are the only weeks in which the resultant temperature was above the average, and may fairly be considered the only warm periods during the seven months.

This persistency of low temperature is to be traced over the whole of the past twelve months, commencing with the beginning of August 1885. To the three warm weeks already mentioned there must be added those of November 9 and 30, December 21, and January 4, making seven in all, and these represent the only warm weeks throughout the entire period, and are the only weeks in which the mean temperature for the whole of the British Islands was above the average.

The following table, which is compiled from the Weekly Weather Reports for the fifty-two weeks ending August 2, 1886, shows the number of weeks with the temperature in excess or defect of the average, and the extent of the deficiency for the several districts. The averages used for the comparison are for the twenty years 1861–1880.

	Weeks above the average	Weeks in agreement with average	Weeks below the average				
			1°-2°	3°-4°	5°-6°	7°-8°	9°-10°
Scotland, N. ...	7	6	15	16	6	2	—
Scotland, E. ...	11	4	17	10	7	3	—
England, N.E. ...	12	2	14	13	8	3	—
England, E. ...	9	3	13	11	12	1	3
Midland Counties ...	11	2	12	13	9	2	3
England, S. ...	10	7	14	10	6	2	3
Scotland, W. ...	10	1	23	9	5	4	—
England, N.W. ...	7	—	17	12	11	2	3
England, S.W. ...	7	6	14	13	7	2	3
Ireland, N. ...	9	1	18	15	5	4	—
Ireland, S. ...	8	5	19	10	7	2	1
Channel Islands ...	6	9	20	11	5	—	1

From this it is seen that the highest number of weeks during the year with the temperature above the average was twelve in the north-east of England, whilst the lowest was six in the Channel Islands.

Throwing the weekly values together so as to form a monthly result, it is seen that November 1885 is the only month of the last twelve in which the resultant temperature for the whole of the British Islands was above the average, and then the excess only amounted to 1°; of the remaining eleven months, one was in agreement with the average, one had a defect of 1°, four had a defect of 2°, three a defect of 3°, and two a defect of 4°. The three consecutive months having the greatest deficiency of temperature were January to March, the defect averaging fully 3° for the entire period.

The rainfall for the same twelve months was above the average during the six months September, October, and November 1885, and January, May, and July 1886, the excess being larger in England than in Scotland or Ireland. It was in fair agreement with the average in March and April, and in defect in the four months August and December 1885, and February and June 1886.

CHAS. HARDING

THE PLIOCENE DEPOSITS OF NORTH-WESTERN EUROPE

In the series of stratigraphical monographs on which the Geological Survey is engaged, the preparation of the volume treating of the Pliocene deposits has been assigned to Mr. Clement Reid. In pursuance of the plan on which these works are being written, I requested him to visit some of the Continental regions where deposits of corresponding age are best developed, and a personal acquaintance with which would extend his knowledge of their English equivalents. He has accordingly spent some time recently in Belgium and Holland, and among other localities visited the well-known exposures of the Diestian beds around Diest and Antwerp. The sections there laid open, the remarkable assemblage of organic remains contained in them, and the peculiar condition in which the shells at Diest have been preserved led him on his return to this country to re-examine the curious deposit of ironstone at Lenham, on the North Downs, in which, so far back as 1857, the occurrence of Pliocene shells was announced by Prof. Prestwich. Doubt was cast upon this identification of the age of these shells: by many geologists they were looked upon as Lower Eocene, though their original discoverer has consistently maintained his opinion. Mr. Reid has now been fortunate enough to obtain a considerable number of additional species that settle beyond doubt the Pliocene age of the Lenham beds, and thus confirm the view of the veteran Oxford Professor. The establishment of this point raises questions of such wide interest in geology that I feel justified in anticipating the appearance of the memoir in which the facts will be detailed. At my request Mr. Reid has drawn up the following report, which briefly embodies the facts he has brought to notice, and touches upon some of the problems which they suggest.

ARCH. GEIKIE

Some years ago Prof. Prestwich announced the discovery of beds of Pliocene age at a height of over 600 feet on the North Downs (*Quart. Journ. Geol. Soc.*, vol. xiv. p. 322). The bad preservation of the fossils, however, led Mr. S. V. Wood, who examined them, to mark all the species as doubtful, though he was inclined to agree that they were probably Pliocene. Owing to the unsatisfactory nature of the palæontological evidence, and apparently also to an accidental mixture of Eocene fossils from other localities, this discovery has been discredited or ignored, though Prof. Prestwich himself has always maintained its accuracy.

Recently, while preparing an account of the British Pliocene beds for the Geological Survey, it has been necessary for me to examine any outlying deposits which have been considered to belong to that period. For this purpose I paid a second visit to Lenham, near Maidstone, having several years ago examined that locality with no satisfactory result, owing to the obscurity of the sections. A number of blocks of fossiliferous ironstone were obtained from pipes in the Chalk—just as the original specimens were found. These were brought to London, carefully broken up, and impressions taken from the moulds of fossils with which the ironstone was filled. By this means a series of casts was obtained very much better than the obscure impressions so doubtfully determined by Mr. S. V. Wood. The result of the examination of these fossils has thoroughly corroborated Prof. Prestwich's view, for there is not a single Eocene species among them. With two or three exceptions they are all known Pliocene forms; some are new to England, though occurring in France and Italy.

The species obtained were the following, my determinations in every case being indorsed by Messrs. Sharman and Newton:—

Pyrula reticulata, Lam.	*Arca lactea*, Linn.
Nassa prismatica, Broc.	,, *diluvii*, Lam. (new to England)
Ringicula ventricosa, J. Sow.	*Leda*, sp. (not *L. myalis*)
Pleurotoma turrifera (?), *Nyst.*	*Nucula*, sp.
,, *consobrina* (?), Bellardi (Upper Miocene)	*Diplodonta rotundata*, Mont., oval var.
,, *Jouanneti* (?), Des M. (Upper Miocene)	*Cardium*, 3 sp.
Trophon muricatus, Mont.	*Cardita senilis*, Lam.
Cerithium tricinctum, Broc.	*Astarte Basteroti*, Laj.
Turritella incrassata, J. Sow.	,, *gracilis*, Munster
Fusus, sp. (= an undetermined Red Crag species)	*Tapes*, sp.
Scalaria clathratula, Turt.	*Gastrana fragilis*, Linn.
Margarita trochoidea (?), S. V. Wood, var.	*Tellina donacina*, Linn.
Trochus millegranus, Phil.	*Mactra*, sp.
Natica, 2 sp.	*Lutraria elliptica*, Lam.
Bulla lignaria, Linn.	*Teredo* (?)
Ostrea, sp. (young)	*Terebratula grandis*, Blum.
Pecten, 2 sp.	*Lunulites* (?)
Pectunculus glycimeris, Linn.	*Balanus*, sp.
	Diadema (?)

The first thing that strikes one in this list is that the whole of the living species are southern forms, and the nearest allies of the extinct species belong to much warmer seas than ours. This, and the general character of the fauna, and proportion of extinct species, lead me to refer the beds to the Older Pliocene period, and to correlate the deposit with our Coralline Crag and with the Lower Crag or Diestian of Belgium. The fossiliferous clay of St. Erth, in Cornwall, I also think is of about the same age, and not newer.

Some curious questions are raised by these recent discoveries, and by others equally remarkable in Belgium and Holland. We now find that, instead of the Older Pliocene period being one of elevation, there must have been wide-spread submergence over great part of Western Europe. A few years since the Coralline Crag was generally considered to be our only representative of the period, and as it did not rise much above the sea-level, it was often assumed that much of the rest of England was dry land. Now it is known that Pliocene beds cap the highest parts of the North Downs, and from the undisturbed position of the shells, unworn, and generally with the valves united, it is evident that the depth of water must have been sufficient to prevent the deposits at the bottom being affected by storms. A subsidence sufficient to allow only 20 or 30 fathoms of water over the highest parts of the North Downs (and the depth in which the Lenham shells lived could hardly have been less) would submerge the whole of the east and south of England, except a few hills.

In Cornwall also there appears to have been a submergence to a considerable depth, for the St. Erth clay was evidently laid down in still water, which would not be found at a less depth than 40 or 50 fathoms in a district exposed like this to the Atlantic swells. The fossils also in that clay point to some considerable depth of water, while the general flattened contour of the country suggests that this district has nearly all been submerged within a comparatively recent period. The lower parts of Cornwall form a smooth, undulating country, out of which rise abruptly the higher hills. Round one of these hills—St. Agnes Beacon—coarse sand is found at a high level. This is probably a beach deposit of the same age as the clay at St. Erth, though all fossils have now disappeared from it. Cornwall seems at that period to have formed a scattered archipelago like the Scilly Islands.

Among the hard rocks of Cornwall denudation does not appear much to have changed the general configuration of the country since the Older Pliocene period. Moreover the Pliocene deposits were probably never continuous or thick, but merely formed patches in sheltered places and round the shores, the rest of the sea-bottom being rocky. In the south-east and east of England, however, the case was different, for the rocks of that region are soft and much more easily denuded. The position of the Lenham beds, at the very edge of an escarpment, over 600 feet above the sea, indicates that the great valleys of the Thames and Weald have to a large extent been excavated since Pliocene times.

On the other hand, the question arises whether the elevation of the Wealden axis was still in progress during the Pliocene period. That the greater part of this enormous disturbance had been completed before that period seems proved by the absence of any Pliocene beds in the Hampshire or London basins in the synclinal folds parallel with the Weald. But there is possibly evidence of less violent movements of upheaval in the different levels at which Older Pliocene beds now occur. We find the Coralline Crag slightly above the present sea-level, the Lenham beds 610 feet above, while at Utrecht deposits of about the same age are found at a depth of at least 1140 feet below the sea, and their bottom has not yet been reached.[1] If the movements in North-Western Europe have been regular and of equal amount everywhere, then, taking the Downs near Lenham as the starting-point, with a depth of 20 fathoms, we should expect to find in the Coralline Crag the deposits and fauna of 120 fathoms, and at the bottom of the well at Utrecht those of 310 fathoms.

A Pliocene fauna of over 300 fathoms would be most interesting to examine, but of such a fauna no trace has yet been detected anywhere in North-Western Europe. The Pliocene deposits, though now at such different levels, are shown by their included fossils to have been laid down in about the same depth of water. Though differing much in mineral composition at the various localities, they nevertheless agree as closely in regard to their shells as the very different nature of the sea-bottoms would lead us to expect. The whole 1143 feet of Pliocene and Pleistocene beds at Utrecht consists of essentially shallow-water deposits, pointing to a continuous depression.

Were we to assume that the present positions of the Pliocene deposits of the north-west of Europe represent the relative depths at which the beds were originally laid down, a curious difficulty would present itself in any attempt to compare the Pliocene and recent sea-bottoms. Any deep depressions in the seas around England are now filled with cold water and contain an Arctic fauna. In similar depths during the Pliocene period one would expect to find a similar fauna, unless there existed, as in the Mediterranean, a barrier to cut off the Polar currents, or unless there was at that time no cold area at the Pole. Neither of these explanations seems sufficient, and it is more probable that those geologists are right who maintain that the direction of the movements in areas of subsidence or elevation remains the same during long periods. Holland may thus have undergone continued, though probably intermittent, depression since the early part of the Pliocene period; thus allowing the accumulation of a great thickness of shallow-water Newer Tertiary beds. The axis of the Weald, including the Downs near Lenham, has been correspondingly elevated. Suffolk was little affected, and the deposits were therefore, in that district, thin and largely of organic origin.

I do not bring forward these conclusions as to elevation and submergence as indisputable facts, but merely as the results of my recent studies in the Pliocene beds at home and on the Continent. Any day new discoveries may profoundly modify our views, but the curious facts will remain, that Northern Europe has yielded only a shallow-water Pliocene fauna, and no trace of boreal outliers such

[1] See Dr. J. Lorié, "Contributions à la Géologie des Pays-Bas," *Archives du Musée Teyler*, ser. ii. vol. ii. part 3.

as occur in our existing seas—and this notwithstanding the very different levels at which Pliocene beds now occur

CLEMENT REID

EARTHQUAKE-RECORDERS FOR USE IN OBSERVATORIES

TWO years ago the writer described in NATURE (vol. xxx. pp. 149 and 174) some of the instruments which he had designed and used in Japan for the registration and analysis of earthquake movements. In response to applications from the directors of several observatories, who wished to add seismometric apparatus to their other equipment, arrangements were some time ago made with the Cambridge Scientific Instrument Company for the manufacture of instruments by aid of which the observation of earthquakes might become part of the ordinary work of any meteorological or astronomical station where such movements occasionally occur. In the design of these seismographs the object has been kept in view of

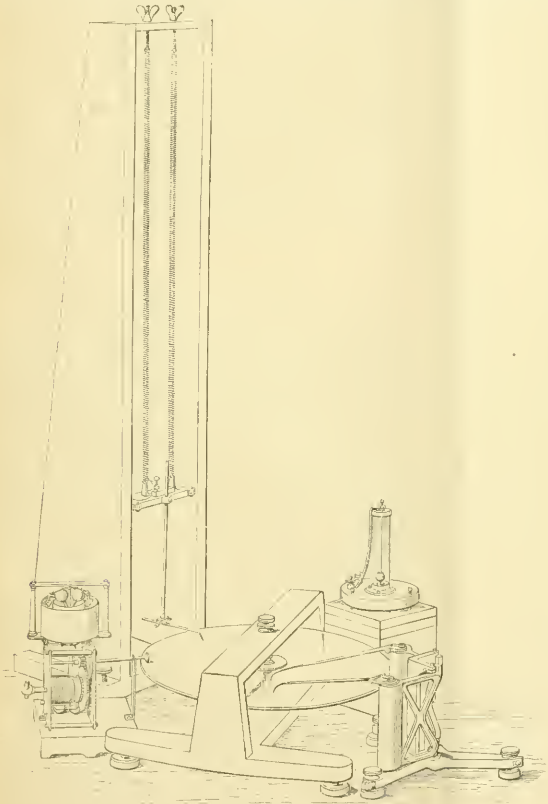

FIG. 1.—Complete three-component seismograph, for motions in all direction.

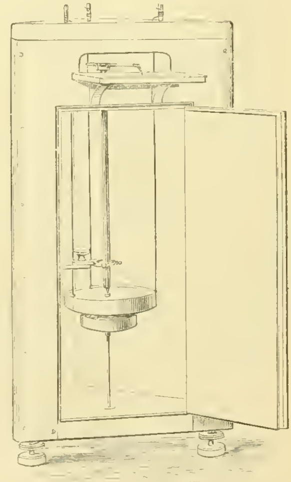

FIG. 2.—Duplex pendulum seismograph, for horizontal motion.

making them easily capable of use by observers who have not made seismometry a special study. They are entirely self-recording, and require little attention during the long intervals which must, in most situations, be expected to elapse between one period of activity and the next.

One group of instruments is arranged to give a complete record of every particular of the movement by resolving it into three rectangular components—one vertical and two horizontal—and registering these by three distinct pointers on a sheet of smoked glass which is made to revolve uniformly by clockwork. A single earthquake always consists of many successive displacements of the ground; hence the record traced by each pointer on the moving plate is a line comprising many undulations, generally very irregular in character. The amplitude, period, and form of each of these are easily measured, and by compounding the three we obtain full information regarding the direction, extent, velocity, and rate of acceleration of the movement at any epoch in the disturbance.

This group of instruments is shown in Fig. 1. In the centre is the plate of smoked glass, which gets its motion

through a friction-roller from a clock furnished with a centrifugal governor, acting by fluid-friction, and balanced so that its speed is not sensibly affected by the shaking of the ground. The clock is started into motion by means of a Palmieri seismoscope, which appears in the figure behind the plate, on the right. This is a small common pendulum whose bob carries at the bottom a piece of stiff platinum wire that projects into a recess in a cup of mercury below—the recess being formed by an iron pin standing lower than the surface of the surrounding mercury. On the slightest shaking of the ground, contact with the edge of the mercury takes place, and this closes a circuit which releases an electro-magnetic detent and starts the clock. This occurs during the preliminary tremors which are usually found in advance of the main movements of an earthquake. The same circuit starts another clock (of the escapement type) which fulfils two functions. It marks time on the revolving plate during a part of the first revolution, and then continues to go as an ordinary clock, so that, by inspecting its dial afterwards, the interval which has elapsed from the occurrence of the earthquake is known, and the date of the shock in hours and minutes is thus determined with as much precision as the phenomenon admits of. This part of the apparatus is omitted from the figure. The two horizontal components of motion are recorded by a pair of horizontal pendulums, set at right angles to each other, but with their indices inclined so that they write side by side on one radius of the plate. The pendulums are supported on a single stand, but with independent adjustments for position and stability. Each has two pivots, consisting of hard steel points, which turn in sapphire centres. At the pivots and at the tracing-points every effort has been made to avoid friction. The indices are of aluminium, and a part of their weight is taken by springs (not shown in the figure), so that their pressure on the plate may be no greater than is necessary to produce a trace on the sooty film. The vertical component of motion is recorded by the instrument which appears behind the clock. A massive bar, free to move vertically about a horizontal axis, is held up by a pair of long spiral springs. Its equilibrium is made nearly neutral by applying the pull of the springs at a suitable distance below the horizontal plane through the axis of support, in the manner described in the article to which reference has already been made. A bell-crank lever with a jointed index gives a multiplied trace of the apparent vertical oscillations of the bar, which correspond to vertical displacements of the ground. In this instrument, as in the others, sapphire centres are used to minimise friction.

Records inscribed on the plate are preserved by varnishing the plate, and using it as a "negative" to print photographs. The motion, as recorded, is magnified to an extent which experience of Japanese earthquakes has shown to be desirable in dealing with disturbances ranging from those which are just recognisable as earthquakes up to those which are to some extent destructive. For great earthquakes, separate apparatus of the same type is designed, in which the multiplying indices are dispensed with, and the scale and style of the other parts are considerably modified.

Another and distinct instrument, also manufactured by the Cambridge Company, is the duplex pendulum seismograph, shown in Fig. 2. A massive bob is hung by three parallel wires from the top of a three-cornered box, and is reduced to nearly neutral equilibrium by being coupled by a ball-and-tube joint to the bob of an inverted pendulum below it. The two form a system which can be made as nearly astatic as is desirable, and so furnish a suitable steady-point for the horizontal part of earthquake movement in any azimuth. The motion is magnified and recorded by a vertical lever geared to the upper bob by a ball-and-tube joint, supported on gimbals from a bracket fixed to the box, and furnished with a jointed index which writes on a fixed plate of smoked glass. Records of the kind which the duplex pendulum gives are of course incomplete in two important particulars: they show nothing of the vertical motion (which, however, is usually a comparatively small part of the whole), and they show nothing of the relation of *time* to displacement throughout the disturbance. But they exhibit very clearly the change of direction which the movements undergo, and the actual direction taken by any pronounced element of the shock. The writer has recently learnt from his former assistant, Mr. Sekiya, now Professor of Seismology in the University of Tokio, that as many as fifteen of the duplex pendulum seismographs are in use by official and private observers in Japan.

The instrument shown in the figures are now on view at the Edinburgh International Exhibition (Court 21, No. 917). Similar sets are being made for the Lick Observatory, California, the Ben Nevis Observatory, and other places. It is scarcely necessary to add that they show the high finish and perfection of workmanship characteristic of the Cambridge Company's manufactures. To Mr. Horace Darwin the writer is especially indebted for a number of suggestions the adoption of which has contributed much to scientific accuracy in details and simplicity in structural arrangements.

J. A. EWING

THE INSTITUTION OF NAVAL ARCHITECTS AT LIVERPOOL

THE Institution of Naval Architects departed this year from their almost invariable custom of holding meetings in London, and had a most successful series of meetings at Liverpool. The papers read were few in number, but they were of special, and, in some cases, unusual interest. The meetings were attended by a large number of the Members of the Institution, as well as Liverpool scientific men, shipowners, underwriters, engineers, and others interested in the subjects of discussion. A local paper was read by Mr. G. F. Lyster, C.E., the Engineer to the Mersey Dock and Harbour Board, upon the Docks of Liverpool; Prof. F. Elgar read a paper upon "Losses of Life at Sea"; Mr. B. Martell upon "The Carriage of Petroleum in Bulk on Over-sea Voyages"; Mr. W. John upon "Atlantic Steamers"; and Mr. W. Parker on the "Progress and Development of Marine Engineering."

Prof. Elgar's paper upon losses at sea has attracted much attention. It contains a general analysis of the losses that happened during the triennial period that has recently caused so much controversy as to whether loss of life at sea is increasing or not, viz. the three years 1881-83. Details are given, in a set of tables appended to the paper, of the steamers and iron sailing ships belonging to the United Kingdom, of and above 300 tons gross register, that were reported to the Board of Trade as foundered or missing during the five calendar years 1881-85. The facts contained in these tables show clearly the great advantage it would be to the shipping community if such information were published periodically in a clear and convenient form. Probably no documents that emanate from any Government Department are more bewildering, or more difficult to extract any tangible information from, than the voluminous and complicated returns of wrecks and casualties, and of lives lost at sea, that are published annually by the Board of Trade. We hope that the attention of the Royal Commission now sitting upon Loss of Life at Sea, has been forcibly directed to the many imperfections and the comparative uselessness of the present published returns that profess to deal with these matters; and that one of the Committee's recommendations will be that something should be done to make them clear and instructive.

There is another cognate matter which we hope will also be dealt with satisfactorily by the Royal Commission, viz.

the manner in which wreck inquiries are now conducted. As matters stand, the evidence obtained at those inquiries, and the rulings that are given by the Courts, have no scientific or practical value. There is no class of quasi-scientific literature that we know of which contains more bad science than is to be found in the rulings of the Wreck Inquiry Courts. Prof. Elgar puts the case very mildly when he says that the returns of the Wreck Inquiry Courts are not all that might be wished as regards the publication of facts connected with losses, and that they are often imperfect and erroneous where difficult technical points are involved. He adds that "this probably arises from the perfunctory character of many of the inquiries; as it has been explained by the Wreck Commissioners that the number of inquiries, and the distant places at which they are sometimes held, often make exhaustive inquiries impossible."

Nothing can be held to excuse imperfect inquiries into the causes of those losses at sea which have formed the subject of so much public discussion and excitement, and respecting which a Royal Commission is now sitting; and nothing would be more likely to promote an increase of knowledge, or to lead to the adoption of precautions for preventing losses, than thorough and trustworthy inquiries into the causes of those losses that so frequently occur.

The conclusions arrived at by Prof. Elgar in his paper, as the result of an examination of the analysis contained in it, are the following:—

(1) The shifting of cargoes is one of the chief causes of the foundering of steamers and iron sailing ships at sea, independently of mere depth of loading.

(2) Dangerous shifting of grain sometimes takes place through hasty and imperfect stowage, inefficient shifting-boards, or weakly-constructed end bulkheads, or through the omission to fit end bulkheads, where such are required on account of the density of the cargo; and dangerous shifting of coal sometimes takes place, because it is carried in compartments that are not fitted with shifting-boards.

(3) Many steamers carrying grain and coal cargoes—notably the class of narrow three-decked steamers built several years ago—are vessels that have insufficient stiffness when fully laden, to resist heeling to a dangerous angle, in the event of cargo shifting or of water getting below.

(4) The effect upon such vessels of the shifting of cargo, and of water below, is generally to hold them over at a considerable angle of inclination, but not to completely capsize them.

(5) Pumping power at the bilges is often an essential condition of preventing loss in such circumstances, and of getting a vessel righted.

(6) The stability of these vessels when laden with the various cargoes they are likely to carry, should be completely determined by calculation before they are sent to sea; and clear instructions, based upon the information so obtained, should be framed for the guidance of those who are responsible for their loading. Such instructions should include particulars of the empty spaces to be left in the 'tween decks, or of the weight of ballast to be carried, or both, for each class of cargo.

(7) All the authentic particulars procurable of ships that have foundered and are missing, and of the circumstances and the manner in which the foundered ships were lost, should be collected and published periodically for the information of the shipping community.

(8) The losses of steamers through the shifting of cargoes seem to be chiefly among the narrow steamers of the three-decked type that were built several years ago. The steamers of that type that have recently been built have more beam and much greater stability than those formerly built, and it may be confidently hoped that the attention which has been given to this matter of late, and the improvements that have consequently been introduced into this type of vessels, will lead to a diminution of losses among them.

Mr. Martell's paper upon "The Carriage of Petroleum in Bulk on Over-sea Voyages" deals very fully with the history of the carriage of petroleum by sea, and the special precautions that are necessary to enable it to be carried safely and economically in ships. Besides those points, however, that are special to the treatment of petroleum as a cargo, there are others which naturally grow out of a consideration of the subject. There is, for instance, the important question of the use of liquid fuel for marine propulsion. The mechanical difficulties involved by this have now been overcome, so that *astatki*, the residuum of crude oil, might be profitably used as fuel for steamers employed upon comparatively short voyages. It is largely and successfully used for marine propulsion on the Caspian Sea, where oil is very cheap and coal is very expensive. The chief obstacle at present to extending the use of this fuel is its cost. The price of *astatki* at Baku varies from 4*d.* to 1*s.* 3*d.* per ton; the carriage by rail to Batoum raises the cost at that port to about 1*l.*; and after adding freight charges for bringing it to this country, its total cost on delivery would, according to Mr. Martell, be not less than 2*l.* 2*s.* From these figures it must be evident that while the best steam coal can be shipped at Cardiff for about 9*s.* per ton, liquid fuel cannot be economically used in competition with it. As the cost of transport of liquid fuel from Baku to Batoum becomes reduced—and this can only be a question of time—there is no doubt that liquid fuel will come into general use for local steamers, and most likely for many steamers trading in the Mediterranean.

Mr. W. John refers, in his paper upon "Atlantic Steamers," to several matters that are of importance to the travelling public. He advocates the adoption of twin-screws in first-class Atlantic steamers as a provision against total breakdown in the event of a shaft, or of any other vital part of the propelling machinery, giving way. He also advocates a middle-line bulkhead, and greater internal subdivision generally, so that ships may be more safe in the event of a compartment being bilged through collision. Mr. John states that improved designs for the Atlantic passenger steamers of the future now form the subject of work and investigation in the drawing-offices of several shipyards. The developments that are taking place are, doubtless, generally in the direction of providing greater safety against accidents to the hull of the ship, or to the propelling machinery, by means of greater internal subdivision and twin-screw engines. Higher speeds than any yet realised are being contemplated by building purely passenger vessels that will carry no cargo; and many improvements of details, which are in the direction of making the accommodation for passengers more like that furnished by a first-class hotel, are also being devised.

Mr. Parker's paper upon "The Progress and Development of Marine Engineering" forms a supplement to one read by Mr. F. Marshall before the Institution of Mechanical Engineers at Newcastle-on-Tyne, in 1881. Mr. Parker traces the progress that has been made in economy of steam propulsion since the introduction of the triple expansion-engine by Mr. A. C. Kirk in 1874. Mr. Kirk fitted triple expansion-engines to the *Propontis* for Mr. W. H. Dixon, in that year, with boilers designed for a working pressure of 150 lbs. per square inch; but the boilers did not prove satisfactory, and were ultimately removed. The next triple expansion-engines were those of the yacht *Isa*, designed by Mr. A. Taylor, of Newcastle-on-Tyne, in 1877; and those of Messrs. G. Thompson and Sons' steamer, *Aberdeen*, which were constructed by Mr. A. C. Kirk, in 1881, for a steam pressure of 125 lbs. per square inch. The *Aberdeen* was the real pioneer vessel of the triple expansion type of engine; as it was proved in her that triple expansion-engines could be made not only to fulfil all the ordinary conditions of working at

sea, but to effect a great economy in coal-consumption. Since then the new system has come rapidly into use, and shipbuilders and marine engineers are now looking in the direction of triple and quadruple expansion-engines for the economical advantages of high-pressure steam in future ships.

It is estimated that the present triple-expansion marine engine, with 150 lbs. of steam-pressure, has an advantage of from 20 to 25 per cent. in economy of coal consumption, over the ordinary compound engine with 90 lbs. pressure, which it is rapidly supplanting. These results have been achieved through a clear appreciation of the waste of energy which is caused by the alternate heating and cooling of a steam cylinder that takes place in consequence of the difference of temperature at which the steam enters and leaves it. The steam jackets introduced by James Watt as a cure for this were imperfect and wasteful in their action. An effectual remedy has been found as the result of many years of study and experiment by men of science and engineers, by expanding the steam successively in several cylinders, so as to make the variation of the temperature of the steam in each cylinder as small as possible.

NOTES

We greatly regret to announce the death of Mr. George Busk, F.R.S., the well-known surgeon and naturalist, in the seventy-eighth year of his age. We must reserve a detailed notice of Mr. Busk's life and work.

Geologists will be sorry to hear of the death of Mr. Gerrard Kinahan, son of the well-known geologist of the Geological Survey of Ireland. Last October he accepted an appointment in the service of the National African Trading Company. The last letter received from him gave an interesting account of his explorations up the southern tributaries of the Niger. He died on May 23 from a wound with a poisoned arrow in a fight with the native tribes at a place called Anyappa. His training as a chemist and geologist at the College of Science in Dublin and also at the School of Mines in London had thoroughly qualified him for original research, and his quietly enduring temperament and kindliness of nature augured a most successful scientific future, whether at home or abroad. But he has been cut down on the very threshold of his career—another young victim to the dangers of African exploration.

The death is announced of Dr. R. J. Mann, F.R.C.S., aged sixty-nine. Dr. Mann was for three years President of the Meteorological Society, and was a Member of the Astronomical, Geographical, Photographic, and other Societies. He gave up his medical practice to take a Government appointment in Natal, where he served as head of the Education Department and Medical Officer for many years. On his return, about 1864, he became Emigration Agent for the Colony, and when, some ten years later, he resigned that post, he devoted himself to his favourite scientific pursuits. He was a popular and prolific writer. The protection of buildings from lightning was a subject on which he wrote a good deal, and for which he did much valuable work.

M. Chevreul, the illustrious French chemist, will complete his hundredth year on Monday next. A grand *fête* at the Museum in honour of the occasion is being organised. Delegations from foreign countries as well as from the provinces are expected. In one of the *salles* at the Museum there is to be an exhibition presenting a *résumé* of the scientific labours and discoveries of M. Chevreul. The banquet will be at noon, in order that the famous centenarian may himself be present.

Our Vienna correspondent writes:—"Dr. von Frisch, having recently experimented on preventive inoculations for hydrophobia, has made a preliminary communication to the Vienna Academy of Sciences, in which he states that it was impossible for him to prevent the breaking out of rabies by means of Pasteur's method if the infecting virus (of at least fourteen days' incubation) were administered to previously healthy animals by trepanning. This latter method of artificial infection of animals Dr. von Frisch suggests to be the only safe one. He made his experiments on rabbits and on dogs. At first sixteen healthy rabbits were trephined, and the virus (of sixteen days' incubation) was injected under the dura mater. Fifteen of these rabbits were then subjected at intervals to the usual preventive inoculations, the remaining one not being inoculated. All these animals except one, which, as Frisch believes, was not sufficiently infected, died between the fourteenth and thirty-third day after infection, with symptoms of rabies, and if particles of their spinal cord were injected into healthy rabbits, the latter also became rabid. Similar experiments were then made on dogs, and with the same results. But a series of rabbits infected by subcutaneous injection of the virus, and then treated by Pasteur's method, continue healthy up to the present time."

The Grosvenor Museum for Chester and North Wales was opened at Chester on Monday by the Duke of Westminster. The new museum is intended as the home of four influential local societies—namely, the Chester Society of Natural Science, founded by Charles Kingsley; the Chester Archæological Society, which is closely associated with the name of the late Dean Howson; the Chester Schools of Art; and the Chester Science Classes. The first floor is devoted entirely to science, except one room to be used as a laboratory, a committee-room, and a model-room for the school of art. The upper floor is entirely devoted to the school of art. In the several rooms there are exhibited specimens illustrative of the natural history of the district, water-colour drawings, collections of antiquities, oil paintings, wood carvings, a collection of pictures by members of the Art Club, appliances for science teaching, memorials of Canon Kingsley and Dean Howson, a collection of objects illustrative of Oriental art, a magnificent collection of tapestry, choice embroidery, lace, porcelain, textile fabrics, &c.

The autumn congress of the Sanitary Institute of Great Britain will be held in the city of York on September 21 and following days, under the Presidentship of Sir T. Spencer Wells, Bart.

The summer meeting of the Institution of Mechanical Engineers will be held on Tuesday morning, August 17, and Wednesday morning, August 18, at 25, Great George Street, Westminster. The following papers have been offered for reading and discussion after the address by the President:—Experiments on the steam-jacketing and compounding of locomotives in Russia, by M. Alexander Borodin, of Kieff; on the working of compound locomotives in India, by Mr. Charles Sandiford, of Lahore; description of a portable hydraulic drilling-machine, by M. Marc Berrier-Fontaine, of Toulon; description of the Blackpool electric tramway, by Mr. M. Holroyd Smith, of Halifax; on triple-expansion marine engines, by Mr. Robert Wyllie, of Hartlepool.

The French Association for the Advancement of Science begins its annual meeting to-day at Nancy.

The lectures recently delivered at Oxford by Prof. Sylvester on his "New Theory of Reciprocants," will appear in the coming numbers of the *American Journal of Mathematics*. The lectures are presented in quite simple style, and will be exceedingly interesting to all students of the modern algebra, or, more accurately, of the theory of invariants. The first eight or nine lectures will appear in the forthcoming number of the *Journal*, vol. viii. No. 3.

A Society for the study of anthropology has been founded in Bombay. Before the departure of the East Indian mail the

second ordinary meeting of the Society had been held, and Mr. E. Tyrrel-Leith, the President, was able to give a very satisfactory account of its prospects.

THE report of the Directors and Secretary of the City and Guilds of London Institute on the technological examinations of the present year has just been issued. It states that there is a large increase in the number of candidates who presented themselves, and a satisfactory increase in the number of those who have passed. In 1885, 3968 candidates were examined, of whom 2168 passed. In 1886, 4764 candidates were examined, of whom 2627 have passed. Examinations were held this year in 48 subjects. Applications for examination were received in all the 49 subjects, but, as only one candidate presented himself in sugar manufacture, in accordance with the regulations of the Institute no examination was held in this subject. Last year examinations were held in 42 subjects. The subjects in which there has been the greatest increase in the number of candidates are mechanical engineering, plumbers' work, electric lighting, and gas manufacture. One new subject was this year added to the list—namely, brickwork and masonry, in which 99 candidates came up, and of these 57 satisfied the examiners. In addition to the practical examinations in weaving and pattern designing, in metal-plate work, in carpentry and joinery, and in mine-surveying, which had been previously held, a practical examination was held this year for the first time in typography. Seventy-seven candidates presented themselves for this examination, of whom 32 have succeeded in obtaining a certificate. From the returns furnished in November last, it appears that 7660 persons were receiving instruction in the registered classes of the Institute, as compared with 6396 in the previous year. This increase is due partly to increased attendance at some of the classes, and partly to the formation of new classes, the number of classes in connection with the Institute having increased from 263 in the Session 1884-85 to 329 during the past year. These classes were held in 116 different towns of the United Kingdom. 203 prizes have this year been awarded, being an increase of 26 on those granted last year. These awards include 180 money prizes, 65 silver and 138 bronze medals, of which 62 are in the honours grade and 141 in the ordinary grade. Last year there were 177 money prizes, 51 silver and 126 bronze medals.

THE Norwegian Meteorological Institute of Christiania has adopted an ingenious plan for disseminating its weather reports among the farmers, fishermen, &c. Thus, on the brake of every train departing from the capital to any part of the country after 3 p.m. a signal is exhibited indicating the weather to be expected for the ensuing twenty-four hours. These signals are very simple, consisting of red and white triangles, squares, and balls, each of which, or several combined, have their meaning; a white ball, for instance, "fine weather," &c. These signals will also be displayed from the masts of several coasting steamers. The arrangement is in force from July 1 to October 1.

ACCORDING to the official returns of the Minister of Education in Prussia the number of students in philology and the kindred subjects of philosophy and history in that kingdom—now for a considerable time known to be sensibly on the decrease in the field of the ancient classics—has altogether steadily declined from Michaelmas 1881 to Easter 1885. The number of students of philosophy, philology, and history at the Universities of Prussia amounted in the winter session of 1881-82 to 2522, in the summer session of 1882 to 2535, in the winter session of 1882-83 to 2504, in the summer session of 1883 to 2398, in the winter session of 1883-84 to 2311, in the summer session of 1884 to 2258, and in the winter session of 1884-85 to 2181. Within a period of $3\frac{1}{2}$ years, therefore, the decline in the number of students of philosophy, philology, and history has been about 14 per cent.

A LARGE specimen of the lizard tribe imported from Japan into the Colonial and Indian tropical aquarium lately died in the act of extruding her eggs, numbering eight. One of her feet that had become broken during her existence was found to have grown again. A further consignment of turtles has arrived at the aquarium together with a number of eggs, which have been placed in the Chelonian hatchery for incubation. Some fine specimens of foreign oysters have also arrived.

THAT kingfishers possess a remarkable instinct to avoid those fish proving harmful to them is exemplified by the following incident. A correspondent informs us that being infested with these birds he set traps for them in two of his ponds, one containing minnows and the other perch. A capture was effected daily where the minnows were located, but on no occasion was a kingfisher caught near the perch pond. The latter fish are injurious to birds.

M. GASTON TISSANDIER in a recent number of *La Nature* describes the efforts made by himself and his brother to pursue the subject of aërial photography. For this purpose they sought the assistance of M. Paul Nadar, whose father made the first attempts twenty-eight years ago, to take photographs from balloons. An ascent was made on July 2 from Auteuil, the descent taking place after a voyage of about six hours at Ségrie in La Sarthe, the length of the journey being about 180 kilometres. The maximum altitude exceeded 1700 metres. During the voyage M. Nadar succeeded in executing thirty instantaneous photographs, a dozen of which are, M. Tissandier says, unquestionably the most perfect yet obtained from a balloon. These were taken at various altitudes, ranging from 800 to 1200 metres. They were perfect in all details, but lose by reproduction by heliogravure. Those taken at 1200 metres it has been found impossible to reproduce at all, as they lose all their fineness in the process. The apparatus was placed in different positions on the edge of the car, sometimes being almost vertical, sometimes inclined so as to form with the horizon an angle varying from 25° to 45°. The time in each case was 1/250th part of a second. M. Nadar has enlarged some of the photographs with the new Eastmann paper with remarkable success. It is obvious from the illustrations given in *La Nature* that the photographs have suffered in the reproduction, the details being slightly blurred and indistinct, but the streets, principal houses, gardens, &c., are perfectly clear in the two pictures which were taken at altitudes of 800 and 1100 metres respectively.

A RECENT number of the *British North Borneo Herald* contains a report on the climate of North Borneo, by Dr. Walker, the principal medical officer, which is interesting as being the first scientific account of the meteorology of this recent addition to the British Empire. The climate, Dr. Walker says, is noticeable for nothing more than for its equability and the absence of extremes. The temperature, rainfall, winds, natural phenomena generally, and the diseases are, for a tropical country, of the most mild and temperate types. The country is visited by the regular monsoons at the ordinary times; the rainfall near the coast, according to records kept for seven years past, ranged from 156·9 to 101·26, and averaged 124·34. The temperature recorded at the coast has ranged between the extremes of 67°·5 and 94°·5; better arrangements are now being made for observing temperatures. The absence of tornadoes and earthquakes is to be noticed. The only indication at the present day of the existence of volcanic action is a hot spring, which is reported to exist on an island near the coast. The bulk of the report is occupied with information of a more medical kind, such as the chief diseases, and their respective effects on the various races, native and immigrant, in North Borneo; sanitaria, and the like.

AT a recent meeting of the Anthropological Institute at the Colonial Exhibition, Mr. Swettenham, of the Straits Civil

Service, read a paper on the races of the Straits Settlements. Of the Malays he said it was unlikely that they could be indigenous to the peninsula, but where they came from, whether Java, Sumatra, or elsewhere in the Archipelago, is a question which has never yet met with a satisfactory answer. Their own tradition is that they had a supernatural origin, and that they crossed from Sumatra. Up to about 1250 they were pagans, or followed some form of Hindoo worship, but about that time their conversion to Mohammedanism began. Up to this time, Malay, of all the Sumatran languages, had no written character of its own, but then Perso-Arabic characters were introduced, and many Arabic words found their way into the Malay language. Relics of Hindoo superstitions are still found amongst the Malays and Negritos of the peninsula, and the customs even now observed, especially in Perak, on certain occasions savour strongly of devil-worship. As to the Negritos, Mr. Swettenham remarked that the most complete collection of the clothing, weapons, and ornaments of these people ever yet brought together will be found in the Straits Settlements Court of the Exhibition. His own observation led him to divide the Negritos into two widely different sections—the Sakai and the Semang—the former a people of moderate stature and large bones, rather fairer in complexion than Malays, with long unkempt wavy hair standing straight out from their heads; the latter small and dark, with black frizzy hair close to their heads, like that of the Negro races. Some writers have found in the comparison of languages a connecting link between the Negritos of various tribes and Malays, and believe the former to show traces of Melanesian blood. The paper contains many interesting observations on the manufactures of the Malays, and on the customs of these and the Negritos.

We have received two excellent memoirs of American men of science, recently read before the National Academy. The first is by Mr. J. D. Dana, and deals with the life and work of Arnold Guyot; the second, the life of Jeffries Wyman, by Mr. A. S. Packard. In each case the work appears to be done admirably, and a list of the writings of the subject of the memoir is appended. At the beginning of his account of Guyot, Mr. Dana notices as a remarkable fact in the history of American science, that, forty years since, the same Republic of Switzerland lost, and America gained, three men of science who became leading men of the country in their several departments —Agassiz in zoology, Guyot in physical geography, and Lesquereux in palæontological botany. A fourth—De Pourtalès, who accompanied Agassiz—also deserves prominent mention, for he was the pioneer of deep-sea dredging in America. The Society of Natural Sciences of Neuchâtel lost all four to the United States between 1846 and 1848. The memoir of Wyman (the list of whose papers, &c., reaches the number of 1875) concludes with a very touching portrait from the pen of Dr. Oliver Wendell Holmes, and an ode by Mr. Russell Lowell.

Nos. 25 and 26 of *Excursions et Reconnaissances*, which have just reached this country from Saigon, do not contain so much matter of general interest as usual. In both M. Landes continues his collection of the folk-lore of Annam, under the title "Contes et Légendes Annamites." In No. 26 M. Silvestre, an official connected with the administration of native affairs, has a short paper on the Chao tribe of the Hung-hoa province of Tonquin, which is interesting as showing incidentally the vast number of various tribes, or tribes under various names, which exist in French Indo-China. How far they are related to each other and to some earlier race of which they are the fragments is one of the ethnological problems of the future. Lieut. Campion describes a voyage made in a despatch-vessel to various islands lying off the coast of Cochin-China, which have hitherto been unvisited by Europeans; and the indefatigable M. Aymonier continues the publication of an encyclopædic work on Annam.

A recent number of the *American Meteorological Journal* contains an article on the notorious dust-storms of Pekin. These occur in the dry season, especially in winter and early spring. They come on at irregular intervals, perhaps six or eight times in the season, and last about three days. The wind is westerly, most often north-west, and blows fresh or high. The condition of the streets of Pekin, evil as that is, would not account for the heavy clouds of dust that come down with the storm. The mouth and eyes have to be protected from the fine dust, which penetrates the closest room, and makes food to taste gritty. This abundant dust is spread over a large area. It extends eastward from Pekin to the sea, and south-eastward it regularly descends as far south as the Yellow River, and sometimes Shanghai, 10° of latitude away. The writer of the paper says this vast quantity of dust must come from the great deserts of Mongolia. A series of observations during one of these storms showed a fall in the thermometer when it came on, and a rapid change in the barometer, which rose from 786 mm. to 797 mm. making several rises and falls of less magnitude in the meantime. The clouds, which the day before had been unbroken, rapidly cleared away; the sun was so obscured that it could be inspected by the naked eye; it was also set in a ring. The wind showed diurnal variations, the air was dry, and one had a feeling of malaise and nervousness. After the wind went down, the barometer remained high for a day or two, and on its descent there was another, but much less marked, dust-storm. The storm thus appears to have been a gale accompanying an area of high pressure, which came from the Desert of Gobi and travelled eastward. The dryness of the wind and its abundant dust were in part due to this desert, which lies west and north-west of Pekin, and is not far away. In his great work on China, Richthofen discusses the geological effects of these storms, which are observed throughout the south and west of the Desert of Gobi, and further west are much worse than at Pekin.

A late number of the *Journal* of the Asiatic Society of Bengal contains a short memorandum by Prof. Pedler, of the Presidency College, Calcutta, on certain experiments which he has made on the corrosion of the lead linings of Indian tea-chests —a subject of considerable importance in more senses than one. His conclusions are that tea properly manufactured in the ordinary way has no power to corrode lead; but if unseasoned and damp wood is used for the boxes, corrosion of the lead is almost certain, some varieties of wood acting more violently than others. Even with seasoned wood, if it becomes saturated with water, and be then placed in favourable circumstances of heat and moisture, corrosion takes place. The active agent, he thinks, does not exist ready formed in unseasoned wood, but is produced by a secondary action from the constituents of the wood. The corrosion is not due usually to contact action between the lead and the wood, but a volatile substance is gradually produced from the unseasoned wood. The corroding agent is usually acetic acid in the presence of moist air and carbonic acid, but other acids of the same series are sometimes produced and also act on the lead, and in the case of butyric and valeric acids the incrustation is of a greenish yellow, while that from acetic acid is whitish or yellowish. The lead being corroded by these acids, which are produced by the decomposition of substances known to be present in the woods, the tea takes up the disagreeable odour of the latter after they have undergone the change in which acetic, butyric, and the other acids are formed, and will thus become deteriorated.

The additions to the Zoological Society's Gardens during the past week include a Common Fox (*Canis vulpes* ♂), British, presented by Mr. J. W. Morgan; a Spotted Ichneumon (*Herpestes nepalensis*) from Nepal, presented by Mr. Herbert W. Brown; a Common Polecat (*Mustela putorius*), British, presented by Mr. William Buckley; a Red-crested Cardinal (*Paro-*

aria cucullata) from South America, presented by Mr. W. E. Ayerst; four Florida Tortoises (*Testudo polyphemus*) from Florida, presented by Mr. Hugh Bellas; a Common Viper (*Vipera berus*) from Hampshire, presented by Mr. Gerald Waller, F.Z.S.; a Brown-throated Conure (*Conurus æruginosus*) from South America, a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, a Macaque Monkey *Macacus cynomolgus*) from India, deposited; a Bandicoot Rat (*Mus bandicoota*), a Bronze-spotted Dove (*Chalcopelia chalcopilos*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *AUGUST* 15–21

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 15

Sun rises, 4h. 47m.; souths, 12h. 4m. 16·6s.; sets, 19h. 21m.; decl. on meridian, 14° 1′ N.: Sidereal Time at Sunset, 16h. 57m.

Moon (one day after Full) rises, 19h. 12m.*; souths, 0h. 13m.; sets, 5h. 19m.; decl. on meridian, 12° 13′ S.

Planet	Rises	Souths	Sets	Decl. on meridian

TENTH ANNIVERSARY OF THE JOHNS HOPKINS UNIVERSITY

THE tenth anniversary of the Johns Hopkins University at Baltimore was celebrated on April 26 last. Of the addresses delivered on that occasion we reprint two, the second of which reviews the work of this distinguished institution since its foundation. The work of the University in every department of human knowledge is well-known and appreciated in this country, and it is unnecessary to add a word to the address of Dr. Thomas, beyond expressing a cordial hope that the future may, in the words of the very appropriate ode read on the occasion, be

"Smooth course and splendour of the sunset-smiles."

The following is the address delivered by Prof. Henry A. Rowland, Ph.D., who took for his subject "The Physical Laboratory in Modern Education."

"From the moment we are born into this world down to the day when we leave it, we are called upon every moment to exercise our judgment with respect to matters pertaining to our welfare. While nature has supplied us with instincts which take the place of reason in our infancy, and which form the basis of action in very many persons through life, yet, more and more as the world progresses and as we depart from the age of childhood we are forced to discriminate between right and wrong, between truth and falsehood. No longer can we shelter ourselves behind those in authority over us, but we must come to the front and each one decide for himself what to believe and how to act in the daily routine and the emergencies of life. This is not given to us as a duty which we can neglect if we please, but it is that which every man or woman, consciously or unconsciously, must go through with.

"Most persons cut this Gordian knot, which they cannot untangle, by accepting the opinions which have been taught them and which appear correct to their particular circle of friends and associates: others take the opposite extreme, and, with intellectual arrogance, seek to build up their opinions and beliefs from the very foundation, individually and alone, without help from others. Intermediate between these two extremes comes the man with full respect for the opinions of those around him, and yet with such discrimination that he sees a chance of error in all, and most of all in himself. He has a longing for the truth, and is willing to test himself, to test others, and to test nature until he finds it. He has the courage of his opinions when thus carefully formed, and is then, but not till then, willing to stand before the world and proclaim what he considers the truth. Like Galileo and Copernicus he inaugurates a new era in science, or, like Luther, in the religious belief of mankind. He neither shrinks within himself at the thought of having an opinion of his own, nor yet believes it to be the only one worth considering in the world; he is neither crushed with intellectual humility, nor yet exalted with intellectual pride; he sees that the problems of nature and society can be solved, and yet he knows that this can only come about by the combined intellect of the world acting through ages of time, and that he, though his intellect were that of Newton, can, at best, do very little toward it. Knowing this he seeks all the aids in his power to ascertain the truth, and if he, through either ambition or love of truth, wishes to impress his opinions on the world, he first takes care to have them correct. Above all, he is willing to abstain from having opinions on subjects of which he knows nothing.

"It is the province of modern education to form such a mind, while at the same time giving to it enough knowledge to have a broad outlook over the world of science, art, and letters. Time will not permit me to discuss the subject of education in general, and, indeed, I would be transgressing the principles above laid down if I should attempt it. I shall only call attention at this present time to the place of the laboratory in modern education. I have often had a great desire to know the state of mind of the more eminent of mankind before modern science changed the world to its present condition and exercised its influence on all departments of knowledge and speculation. But I have failed to picture to myself clearly such a mind, while, at the same time, the study of human nature, as it exists at present, shows me much that I suppose to be in common with it. As far as I can see, the unscientific mind differs from the scientific in this, that it is willing to accept and make statements of which it has no clear conception to begin with, and of whose truth it is not assured. It is an irresponsible state of mind without clearness of conception, where the connection between the thought and its object is of the vaguest description. It is the state of mind where opinions are given and accepted without ever being subjected to rigid tests, and it may have some connection with that state of mind where everything has a personal aspect and we are guided by feelings rather than reason.

"When, by education, we attempt to correct these faults, it is necessary that we have some standard of absolute truth: that we bring the mind in direct contact with it, and let it be convinced of its errors again and again. We may state, like the philosophers who lived before Galileo, that large bodies fall faster than small ones, but when we see them strike the ground together, we know that our previous opinion was false, and we learn that even the intellect of an Aristotle may be mistaken. Thus we are taught care in the formation of our

opinions, and find that the unguided human mind goes astray almost without fail. We must correct it constantly and convince it of error over and over again until it discovers the proper method of reasoning, which will surely accord with the truth in whatever conclusions it may reach. There is, however, danger in this process that the mind may become over-cautious, and thus present a weakness when brought in contact with an unscrupulous person who cares little for truth and a great deal for effect. But if we believe in the maxim that truth will prevail, and consider it the duty of all educated men to aid its progress, the kind of mind which I describe is the proper one to foster by education. Let the student be brought face to face with nature: let him exercise his reason with respect to the simplest physical phenomenon, and then, in the laboratory, put his opinions to the test; the result is invariably humility, for he finds that nature has laws which must be discovered by labour and toil, and not by wild flights of the imagination and scintillations of so-called genius.

"Those who have studied the present state of education in the schools and colleges tell us that most subjects, including the sciences, are taught as an exercise to the memory. I myself have witnessed the melancholy sight in a fashionable school for young ladies of those who were born to be intellectual beings reciting page after page from memory, without any effort being made to discover whether they understood the subject or not. There are even many schools, so-called, where the subject of physics or natural philosophy itself is taught, without even a class experiment to illustrate the subject and connect the words with ideas. Words, mere words, are taught, and a state of mind far different from that above described is produced. If one were required to find a system of education which would the most surely and certainly disgust the student with any subject, I can conceive of none which would do this more quickly than this method, where he is forced to learn what he does not understand. It is said of the great Faraday that he never could understand any scientific experiment thoroughly until he had not only seen it performed by others, but had performed it himself. Shall we then expect children and youth to do what Faraday could not do? A thousand times better never teach the subject at all.

"Tastes differ, but we may safely say that every subject of study which is thoroughly understood is a pleasure to the student. The healthy mind as well as the healthy body craves exercise, and the school-room or the lecture room should be a source of positive enjoyment to those who enter it. Above all, the study of nature, from the magnificent universe, across which light itself, at the rate of 186,000 miles per second, cannot go in less than hundreds of years, down to the atom of which millions are required to build up the smallest microscopic object, should be the most interesting subject brought to the notice of the student.

"Some are born blind to the beauties of the world around them, some have their tastes better developed in other directions, and some have minds incapable of ever understanding the simplest natural phenomenon; but there is also a large class of students who have at least ordinary powers and ordinary tastes for scientific pursuits: to train the powers of observation and classification let them study natural history, not only from books, but from prepared specimens, or directly from nature; to give care in experiment and convince them that nature forgives no error, let them enter the chemical laboratory; to train them in exact and logical powers of reasoning, let them study mathematics; but to combine all this training in one and exhibit to their minds the most perfect and systematic method of discovering the exact laws of nature, let them study physics and astronomy, where observation, common-sense, and mathematics go hand in hand. The object of education is not only to produce a man who *knows*, but one who *does*; who makes his mark in the struggle of life and succeeds well in whatever he undertakes; who can solve the problems of nature and of humanity as they arise; and who, when he knows he is right, can boldly convince the world of the fact. Men of action are needed as well as men of thought.

"There is no doubt in my mind that this is the point in which much of our modern education fails. Why is it? I answer that the memory alone is trained, and the reason and judgment are used merely to refer matters to some authority who is considered final, and worse than all they are not trained to apply their knowledge constantly. To produce men of action they must be trained in action. If the languages be studied, they must be made to translate from one language to the other until they have perfect facility in the process. If mathematics be studied, they must work problems, more problems, and problems again, until they have the use of what they know. If they study the sciences, they must enter the laboratory, and stand face to face with nature; they must learn to test their knowledge constantly, and thus see for themselves the sad results of vague speculation; they must learn by direct experiment that there is such a thing in the world as truth, and that their own mind is most liable to error. They must try experiment after experiment and work problem after problem until they become men of action, and not of theory.

"This, then, is the use of the laboratory in general education—to train the mind in right modes of thought by constantly bringing it in contact with absolute truth, and to give it a pleasant and profitable method of exercise which will call all its powers of reason and imagination into play. Its use in the special training of scientific men needs no remark, for it is well known that it is absolutely essential. The only question is whether the education of specialists in science is worth undertaking at all, and of these I have only to consider natural philosophers or physicists. I might point to the world around me, to the steam-engine, to labour-saving machinery, to the telegraph, to all those inventions which make the present age the 'Age of Electricity,' and let that be my answer. Nobody could gainsay that the answer would be complete, for all are benefited by these applications of science, and he would be considered absurd who did not recognise their value. These follow in the train of physics, but they are not physics; the cultivation of physics brings them and always will bring them, for the selfishness of mankind can always be relied upon to turn all things to profit. But in the education pertaining to a University we look for other results. The special physicist trained there must be taught to cultivate his science for its own sake. He must go forth into the world with enthusiasm for it, and try to draw others into an appreciation of it, doing his part to convince the world that the study of nature is one of the most noble of pursuits, that there are other things worthy of the attention of mankind besides the pursuit of wealth. He must push forward and do what he can according to his ability, to further the progress of his science.

"Thus does the University, from its physical laboratory, send forth into the world the trained physicist to advance his science and to carry to other colleges and technical schools his enthusiasm and knowledge. Thus the whole country is educated in the subject, and others are taught to devote their lives to its pursuit, while some make the applications to the ordinary pursuits of life that are appreciated by all.

"But for myself I value in a scientific mind most of all that love of truth, that care in its pursuit, and that humility of mind which makes the possibility of error always present more than any other quality. This is the mind which has built up modern science to its present perfection, which has laid one stone upon the other with such care that it to-day offers to the world the most complete monument to human reason. This is the mind which is destined to govern the world in the future and to solve problems pertaining to politics and humanity as well as to inanimate nature.

"It is the only mind which appreciates the imperfections of the human reason, and is thus careful to guard against them. It is the only mind that values the truth as it should be valued, and ignores all personal feeling in its pursuit. And this is the mind the physical laboratory is built to cultivate."

Dr. Thomas's address was as follows:—

"The foundation and growth of a University is an event of the greatest interest.

"Its functions and use have been elaborately discussed by many modern thinkers and scholars. I shall call your attention to three statements of men of differing schools of thought.

"Goldwin Smith, discussing Oxford University organisation, says:—

"'Experience seems to show that the best way in which the University can promote learning and advance science is—

"'(1) By allowing its teachers, and especially the holders of its great professorial chairs, a liberal margin for private study;

"'(2) By keeping its libraries and scientific apparatus in full efficiency and opening them as liberally as possible;

"'(3) By assisting, through its press, in the publication of learned works which an ordinary publisher would not undertake;

"'(4) By making the best use of its power of conferring literary and scientific honours.'

"Matthew Arnold says, the University 'ought to provide facilities, after the general education is finished, for the young man to go on in the line where his special aptitudes lead him, be it that of languages and literature, of mathematics, of the natural sciences, of the application of these sciences, or any other line, and follow the studies of this line systematically, under first-rate teaching.'

"Again, 'The idea of a University is, as I have already said, that of an institution not only offering to young men facilities for graduating in that line of study to which their aptitudes direct them, but offering to them also facilities for following that line of study systematically under first-rate instruction. This second function is of incalculable importance, of far greater importance even than the first. It is impossible to over-value the importance to a young man of being brought in contact with a first-rate teacher of his matter of study, and of getting from him a clear notion of what the systematic study of it means."

"John Henry Newman says:—'It is a great point, then, to enlarge the range of studies which a University professes, even for the sake of the students; and though they cannot pursue every study which is open to them, they will be gainers by living among those and under those who represent the whole circle. This I conceive to be the advantage of a seat of universal learning, considered as a place of education. An assemblage of learned men, zealous for their own sciences and rivals of each other, are brought by familiar intercourse and for the sake of intellectual peace to adjust together the claims and relations of their respective subjects of investigation. They learn to respect, to consult, to aid each other. Thus is created a pure and clear atmosphere of thought, which the student also breathes, though in his own case he only pursues a few sciences out of the multitude. He apprehends the great outlines of knowledge, the principles on which it rests, the scale of its parts, its lights and its shades, its great and its little, as he otherwise cannot apprehend them.

"'Hence it is that his education is called "Liberal." A habit of mind is formed which lasts through life, of which the attributes are freedom, equitableness, calmness, moderation, and wisdom. This, then, I would assign as the special fruit of the education furnished at a University. . . . This is the main purpose of a University in the treatment of its students.'

"And a great thinker of another generation, George Fox, advised the setting up of schools for instructing 'in whatsoever things were civil and useful in the creation.'

"We may then conclude that a University, wisely planned and faithfully administered, should be able to gather together a company of teachers, distinguished in character and learning; to present courses of study, important and thorough; and to attract scholars mature in age and competent by reason of previous training to pursue special lines of study, in order to fit themselves in a worthy manner for their chosen vocation. It should be wide in its scope and able to supplement the College, and aid students to perfect themselves in many departments of learning. It should provide liberally all the apparatus for this study. It should be rich in laboratories, in books, in instruments. It should endow research and stimulate investigation and discovery. It should be prepared to give results of work done within its halls speedy and wide publicity amongst scholars engaged in kindred pursuits. It should give its contribution to society by training men who are fitted to help in the solution of the problems of the age—scientific, social, political, moral, and religious, both by stimulating the production of books and by contributions to the journals and literature of the day. It should encourage all noble aspirations, conserve all good inheritances of the past, and create an atmosphere of enthusiasm for hard work. It should be able to bestow honours worthy of the name in reward for faithful devotion and for the successful fulfilment of its courses of study. Its work should be known and recognised where learning is known and recognised, and its name should carry weight in other Universities and centres of research in the world of letters.

"Such thoughts as these, I am sure, Judge Dobbin, were in your mind and in the minds of the other trustees to whom was intrusted by our late townsman, Johns Hopkins, the foundation and guidance of this University which was to bear his name. On the completion of the first decade of its existence, in the presence of the trustees and the President and Faculty of the University, before the graduates, the present Fellows, and students of the University, and in the presence of this company of our friends and fellow-citizens, it has seemed fitting to allude to these sentiments as we proceed to consider the progress of this University.

"I am glad to take this opportunity of replying in public to questions such as were asked me by a young Baltimorean, who the other day said: 'Why do Baltimoreans have to go to New Haven or somewhere abroad to learn about the Johns Hopkins? Why do you not tell us what is being done?' In order to do this before a Baltimore audience, I have supposed my friend to have asked the following questions, to which I shall briefly reply:—

"(1) Have great teachers been attracted to the University?

"(2) Have important courses of study been instituted?

"(3) Have students come, and from whence?

"(4) Have patient and successful researches been carried on?

"(5) Has the University gathered together suitable apparatus, &c., for study?

"(6) Have the results of these researches been given by the University to the world?

"(7) Has the work done here been recognised elsewhere?

"(8) Has the training given proved valuable to those who have received it?

"(9) What has the University done for this community?

"The Board of Trustees was incorporated in August 1869, at the instance of Johns Hopkins and during his lifetime. About a year after the death of the founder, in December 1873, the Board was put in possession of the endowment provided by his beneficence, and organised for work. The President of the Board, the late Galloway Cheston, took an active part in the enterprise, and by his advice greatly aided in laying the foundation of the University, and his name will always be honourably associated with its history. The other members of the Board, all of whom had been named by Johns Hopkins, were Reverdy Johnson, Jun., the first Chairman of the Executive Committee, Francis T. King, Lewis N. Hopkins, Thomas M. Smith, William Hopkins, John W. Garrett, Francis White, Charles J. M. Gwinn, George W. Dobbin, George William Brown, and James Carey Thomas.

"*What Great Teachers have been attracted?*—It was soon apparent that the wise and untrammelled directions of Johns Hopkins to his trustees to found a University would attract the attention of those interested in the cause of education, especially in the United States.

"The opportunity of developing an institution suited to the needs of the country was sufficient to draw to Baltimore from across the Continent the then President of the University of California, Daniel C. Gilman, who was named to the trustees as the man best fitted by previous training and devotion to the study of educational methods, to advise and direct the establishment of the new foundation, by his former colleagues of Yale College—by President Eliot, of Harvard University, at once the most renowned and the most venerable institution of learning in the country—by President White, of Cornell University, then in the early days of its growing importance and usefulness—by President Angell, of the University of Michigan, the crowning institution of learning of the well-organised system of public instruction in that great and strong Western State—and by numerous other leading educators. At the request of the trustees Mr. Gilmun came to Baltimore, and after consultation with them accepted the Presidency of the Johns Hopkins University. Under his thoughtful care and constant and laborious effort the plan originally contemplated has been gradually and harmoniously developed.

"Besides President Gilman, the University also drew from across the ocean, from Woolwich, England, Prof. Sylvester, one of the two greatest English mathematicians, and indeed one of the greatest of the world; and from Virginia, in our own land, Prof. Gildersleeve, second to none in his attainments in and devotion to Greek and other classical study—besides younger men whose subsequent career has justified the bright promise of their early years. I shall not mention further by name the present distinguished staff of Professors and teachers, whose work I have alluded to, and who form the permanent renown and attraction of the University.

"I will give a list in chronological order of those gentlemen, not now connected with the University, who, for a longer or shorter period, have lectured here during the past ten years:—

"In Language and Literature, Profs. F. J. Child, James Russell Lowell, W. D. Whitney, C. R. Lanman, Thomas C.

Murray, H. C. G. Brandt, Sidney Lanier (too early lost), Profs. W. W. Goodwin, J. A. Harrison, J. Rendel Harris, Hiram Corson, A. S. Cook, Messrs. George W. Cable, Edmund Gosse, Justin Winsor, A. Melville Bell, Drs. Isaac H. Hall, and W. Hayes Ward; in History and Political Science, Profs. T. M. Cooley, F. A. Walker, W. F. Allen, the lamented J. L. Diman, H. von Holst, Austin Scott, James Bryce, E. A. Freeman (who gave six lectures and imparted a decided impulse to historical study here), R. M. Venable, Messrs. J. J. Knox and Eugene Schuyler; in Archæology and Art, Messrs. W. W. Story, F. Seymour Haden, J. Thacher Clarke, W. J. Stillman. Dr. Charles Waldstein, and Mr. Frederick Wedmore; in Philosophy and Logic, Profs. William James, G. S. Morris, Mr. C. S. Pierce, and Dr. Josiah Royce; in Physical and Mathematical Science, Profs. J. E. Hilgard, J. Willard Gibbs, John Trowbridge, A. Graham Bell, S. P. Langley, Arthur Cayley, C. S. Hastings, and Sir William Thomson; in Chemistry and Biology, Profs. J. W. Mallet, W. G. Farlow, J. McCrady, W. T. Sedgwick, H. Sewall, and W. Trelease.

"At our commencements, anniversaries, and other gatherings, we have heard from Presidents Eliot and White, from Dean Stanley, Dean Howson, Prof. Huxley, Archdeacon Farrar, Chief Justice Waite, Hon. W. M. Evarts, Dr. W. A. P. Martin, Dr. W. B. Carpenter, Hon. S. T. Wallis, J. B. Braithwaite, and others.

"Many of these have been listened to by those not members of the University who were specially interested in their subjects, and it may be fairly said that many eminent and great teachers have been both for long and short periods attracted to the University.

"*What University Courses are here offered, and what Graduate Students have been attracted?*—The courses of University studies that have been pursued have been so often and so fully referred to in the reports and circulars of the University, that I can only enumerate those in higher mathematics, in physics, in chemistry, in mineralogy and petrography, in biology; in Greek, in Latin, in Sanskrit, in Hebrew, in Aramæan, in Arabic, in Assyrian, and in Sumero-Akkadian; in English, in German, in the Romance group of languages, including French, old and modern, Wallachian, Italian, Spanish, Catalan, old Provençal, modern Provençal, and Portuguese; in history, ancient and modern, in political economy, physical and historical geography; in psychology, pedagogics and philosophy, in mental hygiene and ethics. In these studies advanced instruction has been given by all available means, such as lecture, laboratory practice, seminary work, books, models, and plates, in order to fit those who are preparing for teaching or special research.

"That these courses have succeeded in attracting students of mature age is evident from the fact that out of the total number of students (923) enrolled during the decade, 590 have pursued graduate courses, and these 590 came from more than 100 different Universities and Colleges as widely separated as Russia and Japan.

"*What Apparatus and Appliances have been gathered together?*—To aid in the instruction given, the trustees have from the first had in view securing the most convenient and free access to the most modern means of promoting research. They were greatly aided by the existence in Baltimore of a library of unusual value to students—the gift of the late George Peabody, and brought together with much care and diligence by the trustees, the provost, and the librarian of the Peabody Institute—and which has been liberally opened to members of the University. As a supplement to the Peabody collections the University has placed within its own walls 29,000 volumes—a portion of which are standard reference-books needed by all the teachers and students; the remainder are special and often costly books which have been called for by the specialists here engaged in work.

"The plans of the University being at first, from the nature of the case, tentative, the work was begun in two dwelling-houses purchased in 1875, on Howard Street, near Monument Street, and in a hall erected at the time, and named after the founder, which contained an assembly room and accommodations for the library and for the biological laboratory, and in a chemical laboratory built at the same time, and this was for some time the modest seat of the University. The location was found more convenient than had been foreseen, both for students who lived in the city and for those that came from elsewhere, who readily found accommodation in lodgings suited to their taste and means. Easy access was had to the Peabody and other collections of books, as those of the Historical Society, and later of the Pratt Library, and there have gradually grown around the present site complete and well-equipped laboratories. The chemical laboratory has been greatly enlarged and perfected. The biological laboratory adjoining has been erected after plans suggested by years of work and by comparison with foreign institutions of a similar kind, and there is now building near by the physical laboratory, of which Prof. Rowland has been speaking to you to-day. Laboratory work in pathology has been begun in one of the buildings of the Johns Hopkins Hospital, and it is intended to erect the Medical School on a lot now owned by the University, adjacent to the hospital.

"Into these various buildings have been gathered, at the suggestion and under the careful personal supervision of various experts, about 70,000 dols. worth of apparatus of the most approved modern make, thus placing within the reach of investigators the means of pursuing advanced research, as well as enabling students to become familiar by personal use with the newest methods of study and experiment.

"*What Research is carried on, and what has been published?*—The researches which have been made have been many and varied. I cannot refer to the more technical, such as those in mathematics and inorganic chemistry, &c., but briefly to the more easily stated.

"Our knowledge of the nature of the sun, as perceived through the solar spectrum, has received accessions from the beautiful image thrown from the gratings first made here by the agency of a wonderful dividing-engine, the invention of the Professor of Physics. From this image a map of the spectrum has been published, very much more minute than any before made.

"Researches in electricity and magnetism have been made under the auspices of the United States Government, with the co-operation of other nations; the mechanical equivalent of heat has been redetermined; investigations have been conducted in physiology, especially of the heart's action; lower animal life has been studied, especially that of the oyster in connection with the State of Maryland; both here and in Boston the cause of water pollution in great reservoirs has been discovered; the curious geological formation of our own neighbourhood has been brought to notice and has attracted wide attention. The philologians and grammarians have been engaged in the investigation of Greek and Latin syntax; in editing ancient writings, such as Pindar, the newly discovered Greek MSS. of the Teaching of the Twelve Apostles, and part of an old Syriac MS. of the New Testament. Baltimore is now one of the centres for the interpretation of Sanskrit texts and of Assyrian inscriptions. A great contribution has been made to the study of American Institutions, and new methods of historical research and of publication have been initiated.

"It is with satisfaction that I state that these researches have been widely recognised at home and abroad, not as *promises* for the future, but as successful experiments recorded, and conclusions reached which have passed into the history of science. By means of them the fame of the University has been carried into every seat of learning in the world, from Oxford and Cambridge in England, to Tokio, Japan; from the northern and more modern Universities of Sweden and Russia to the ancient seats of learning in Italy and Southern Europe. The exchanges on the shelves of our library, received with almost every foreign mail in return for the six scientific journals published by the University,[1] attest both its importance and its estimation outside its own walls. Besides this, personal and unsolicited testimonials from eminent men are on file in the office which have been received from many quarters.

"These researches, delicate, prolonged, and important, and others not now mentioned, have been made by Professors, Fellows, and advanced students. Indeed the whole plan of Fellowships has in reality been a most practical and efficient endowment of research, and has richly repaid the University and the community in the importance and value of the results obtained.

"Twenty young men who have not quite completed their

[1] (1) The "American Journal of Mathematics," commenced in 1878, now in its eighth volume; (2) the "American Chemical Journal," commenced in 1879, now in its eighth volume; (3) the "American Journal of Philology," commenced in 1880, now in its seventh volume; (4) "Studies from the Biological Laboratory," commenced in 1879, now in its third volume; (5) "Studies in Historical and Political Science," begun in 1882, of which the fourth series is in progress; (6) the "Johns Hopkins University Circulars," begun in 1879, of which forty-nine numbers have been issued.

work as students following masters, but who have gone far enough to indicate that they are possessed of unusual ability, are annually chosen by the Academic Council, and are encouraged by a generous stipend to devote all their time to study which is not of a distinctively professional character. They are chosen because of the hope they give of future achievements, or are selected on the evidence they submit of their previous intellectual attainments. The system here adopted has elsewhere been followed.

"*What has been the Value of this Training?*—Has the training here been of value to the men that have submitted to the severe ordeal of discipline and who have often surrendered honourable and lucrative positions to avail themselves of the advantages offered for research and study? Or, in other words, are the diplomas to be given to-day as testimonials of the University to the attainments of those to whom they are so worthily awarded, of real value to their possessors?

"Of the 69 persons who in these ten years have been admitted to the degree of Doctor of Philosophy, denoting proficiency in various lines of special graduate study, either in letters or in science, 56 have obtained honourable positions as professors and teachers in 32 Universities and Colleges; and of the 90 to whom the degree of Bachelor of Arts has been given, 20 have engaged in teaching in 16 Colleges and high schools.

"I will conclude this part of my subject by quoting the reply made by a graduate student from North Carolina, when asked what he had found here of most use, he replied: 'The freedom of access to able teachers and the stimulant of studying in company with men of maturer minds than one meets elsewhere.'

"*But what has the University done for this community?*—Besides the incidental advantages which must accrue to any community from the presence of a great seat of learning, the trustees have had in mind from the first the special needs of this city and state. At the conclusion of the late war fewer boys were at college than at former periods. Many young men here and further south had foregone college training, and circumstances forbade the sending of others who were growing up. It was manifest that the need of our own people was first a college in order to train for life, or for further university instruction. So side by side with the University has developed the college department of the Johns Hopkins University. This was begun when the discussion of a fixed, a free, or wholly or partly elective college course had not been so warmly debated as at the present time, but it was evident that the wide range which the development of various branches of knowledge has taken since the old arrangement of college studies was effected, and the limited time which can ordinarily be devoted by students to preparation for their life-work, made a readjustment of the college course desirable. This was accomplished here by arranging, after a fixed matriculation, the studies in groups rather than years, and demanding in each group a certain required amount of training in other than the main study of the course. Thus classical students are required to study some science, scientific students some classics, and all to receive a fixed amount of general English training in literature, ethics, philosophy, and modern languages.

"The seven groups for which, in accordance with these principles, arrangements are now made, are these:—

"(1) Classical—corresponding closely with what has been hitherto known in this country as the usual college course.

"(2) Mathematical-Physical—which meets the wants of those who are expecting to enter upon the modern vocations in which rigid mathematical discipline is indispensable.

"(3) Chemical-Biological—which is adapted to those, among others, who expect to enter upon the subsequent study of medicine.

"(4) Physical-Chemical—which is most likely to be followed by students preparing for those scientific pursuits which are neither chiefly mathematical nor chiefly biological.

"(5) Latin-Mathematical—which affords a good fundamental training, without prolonged attention to the study of Greek.

"(6) Historical-Political—which furnishes a basis for the subsequent study of law.

"(7) Modern Language—where French, German, English, and in exceptional cases, other modern languages, take the place of Latin and Greek in the traditional classical course.

"It cannot be said that this arrangement is perfect, but it has worked well, and great effort is made to have it at once liberal and adapted to the exigencies of active life. I should like all the time at my disposal to expand more fully this slight sketch of the college course which lies near my own heart, but must content myself with stating that it has from the first attracted our own boys, to whom great inducement has been held out, and who have proved some of our most enthusiastic and successful students, have won for themselves many of our own Fellowships, and have gone out to positions of importance and emolument. Their number is rapidly increasing, and the University is constantly endeavouring to make closer the connection between the high schools, whether private or public, and the collegiate department of the Johns Hopkins University.

"Various free scholarships are annually offered to students coming from Maryland, Virginia, and North Carolina, and have been held by 150 students from these States. The existence in our midst of such advantages is stimulating our young men to avail themselve of them, and is increasing the number and efficiency of preliminary schools. We have now in the collegiate department 130 students.

"I have thus, in the briefest and most prosaic manner, endeavoured to summarise the work of ten years into the space of twice as many minutes. It has been impossible, although I have not even glanced at the various literary and scientific Societies formed for themselves by the members of the University, nor alluded to the common college life, nor spoken of the work of the Christian Association of the University, which has served an excellent purpose; but yet I think that I have shown that something has been done to bring together great teachers, to start liberal courses of study, to attract students, to collect libraries and apparatus, to stimulate research, to publish results, and have stated in what manner this work has been recognised, and how the needs of this community have been considered.

"But I am sure that in reaching these conclusions you must feel how little has been done in comparison with what is practicable with longer time and greater resources. The perpetuation and enlargement of the University on a broad and liberal foundation should be the pride of every citizen. It is a great trust to be handed down to those who shall succeed us. Let us be careful to see that no detriment happen to it.

"Amidst the jarring of contending factions and classes there needs must be thoughtful men trained to habits of patient investigation and quiet study—amidst the rush of business and competition, men who in secluded laboratories pass hours and days in subtile experiments—amidst the selfishness of politicians and placemen, historians and philosophers and teachers who can recall the lessons of past ages and vindicate the great moral principles which underlie all true progress.

"For these and other great purposes Universities should exist and be richly endowed. They should be few, but strong.

"A president of a growing Western College, last week in Baltimore, emphasised most strongly the importance of adding efficiency to existing Universities in order to make them great centres for training and research. The possessors of great wealth, most frequently in this country accumulated in the course of a single life, have often felt their responsibility in its ultimate destination. They have in many instances, amongst which the course of Johns Hopkins is conspicuous, returned their accumulated gains to the community in noble gifts, founding great institutions of learning and great charities for the training of the future citizen and for the alleviation of human suffering. These should be fostered and enlarged, as has been done at Harvard and at Cornell, in order that the greatest good may be accomplished.

"The training of *men* is after all the most important end of all educational effort. It is to you, young men, the sons of this new foundation, that your teachers and friends look as the best evidence of the success of their endeavour. Your learning, your usefulness, your accomplishments, your high aims and noble character, your achievements, whether in the pulpit or the forum, the college or the laboratory, at home and abroad will afford a continual and living reminder of this, the place of your training.

"To a State founded on the beneficent precepts of Christianity, the walls of its defence must be not the physical strength of its citizens but their moral character. In vain will science harness the powers of the universe unless they are yoked to the chariot of peace and goodwill. In vain will learning and training give efficiency to individual influence and native genius, unless the purposes of the man are noble and far-reaching. The truth which sets free is the truth which warms the heart and expands the sympathies, as well as enlightens the intellect, which is of

Him who is the truth Himself. Let us have confidence in the supremacy of truth. Such has hitherto been the guiding lamp of the Johns Hopkins University. May it ever be the beacon of the future."

SCIENTIFIC SERIALS

A LARGE space in the June number of the *Journal of Botany* is occupied by a long biographical notice, by the editor, of the late Rev. W. W. Newbould, of whom an excellent portrait is also provided. The other articles are almost entirely of local interest.

THE *Journal of the Franklin Institute*, vol. cxxi. No. 724, April 1886.—Lieut. J. P. Finley, tornado study: a useful summary of the principal facts scientifically known respecting tornadoes.—F. E. Galloupe, rapid transit and elevated railroads. This concludes the discussion on this topic.—G. E. Waring, Jun., mechanical appliances in town sewerage; discusses the systems employed in several American cities.—Prof. R. H. Thurston, construction of a large Prony brake. Gives an account of a brake capable of absorbing 540 horse-power.—Dr. W. H. Wahl, summary of engineering and industrial progress for 1885.—Report of Committee on Delany system of multiplex telegraphy.

No. 725, May.—J. M. Hartman, the blast-furnace: a very concise summary of present methods of construction and theories.—Lieut. A. B. Wyckoff, hydrographic work of the U.S. Navy. J. Shinn, the cultivation of flax in the United States.—L. D'Auria, the law of cylinder condensation of steam-engines. The new formulæ indicate that the proper way to decrease cylinder condensation is to increase piston speed.—C. J. Kintner, history of the electrical art in the U.S. Patent Office. An interesting account, in which two early forms of storage battery are described. The author, however, appears to think that nothing can be called an invention unless it has been patented in the United States. There were secondary batteries prior to Kintner's, electric motors prior to Davenport's, and telephones prior to Graham Bell's.—Report of examiners of electrical exhibition on applications of electricity to art productions.

No. 726, June.—Chief Engineer Isherwood, an account of experiments made by Chief Engineers Zeller and Hunt to ascertain the economic effect of using in a non-condensing engine saturated steam alone, and of using it mixed with compressed hot air. No economic saving was effected by this process, as there was not sufficient time for the steam and hot air, which were delivered into the cylinder in separate masses, to become mixed, and the air failed to prevent condensation.—S. L. W., on the Oram system of marine propulsion. This system has twin screws placed forward at about 1/5 of the vessel's length from the bow, in recesses in the sides.—G. W. Chance, the South Street Bridge.—W. Lewis, experiments on the transmission of power by gearing. Valuable researches on the causes of loss of power in worm-gearing and spur-gearing.

No. 727, July.—C. Sellers, Jun., Oliver Evans and his inventions. A biographical notice of this remarkable man, whose prediction of the future of the steam-engine is well known.—O. E. Michaelis, the applications of electricity to marksmanship. This is the first part of the paper, and treats rather of mechanical methods of measuring speed of projectiles, such as Robins's ballistic method.—H. M. Dubois, tests of vehicle wheels.—F. E. Ives, colour-sensitive photographic plates. A compound sensibilisator of fresh blue myrtle chlorophyll with a little eosin is found to be the most sensitive to yellow and green.—Report of Committee on the Phelps induction telegraph. The Committee praise highly this invention for telegraphing to and from a moving train.—Report of Committee on the process and furnace for the reduction of refractory ores and the production of metals, alloys, and compounds, invented by E. H. and A. H. Cowles. Cowles's electric furnace, for reducing ore by means of the voltaic arc between carbon poles, is merely a development of the electric furnace devised by the late Sir W. Siemens. It appears to be eminently suitable for the production of aluminium compounds.—Prof. E. J. Houston, some additional facts concerning the Reis articulating telephone. Gives an account of some recent experiments transmitting speech with the identical apparatus manufactured by Reis and used by him in his lecture before the Physical Society at Frankfort in 1861.

Annalen der Physik und Chemie, vol. xxviii. No. 5, May.—R. Colley, on some new methods for observing electric oscillations, and some applications of them. This paper gives certain relations between the time of oscillation of discharges through a shunt having a great coefficient of self-induction and the capacity of the condenser. Using a standard coil the coefficient of self-induction of which could be determined by its geometrical form, and a normal guard-ring condenser made of three sheets of silvered glass, the capacity of which could equally be determined, the author made experiments from which he deduces a new value of the ratio v, which he gives as $3 \cdot 015 \times 10^{10}$ centims. per second.—Hans Jahn, on the relation of the chemical energy and the current energy of galvanic elements. A discussion of Helmholtz's expression for the secondary heat, together with some determinations made on Daniell's and De La Rue's cells.—E. Riecke, on the pyro-electricity of tourmaline. The first part of this paper summarises the previous researches of Gaugain and others upon the electricity of the tourmaline in relation to its section, length, rate of cooling, &c., and gives an account of some new and careful observations made upon three tourmalines. The second part of the paper is devoted to the development of a mathematical theory of the electricity of the tourmaline, based on the physical hypotheses that the molecules possess an initial electric polarisation, measurable in terms of the electric moment per unit of volume, and dependent upon the temperature, and that there is a surface-conductivity of a certain value. The formulæ appear to agree very well with the observed facts.—T. Ihmori, on the absorption of mercury vapour by spongy platinum. A quantity of platinum, deposited from chloride by formic acid, was found to increase in weight in presence of mercury. The author uses this increase of weight to investigate the figures given by Hertz and by Hagen, for the pressure of mercury vapour at different temperatures. His results are considerably lower than those of Hagen, and a little higher than those of Hertz.—C. Pulfrich, on the elastic reaction of a caoutchouc tube.—A. König, on a new method of determining the modulus of elasticity. Errors of observation are avoided by using two mirrors, the inclination of which altered by the loading of the bar under examination.—Karl Exner, on senseformulæ: lenticular action of non-homogeneous bodies. Discussion of lenticular action of cylindriform disks with parallel plane faces made of materials which, on being cast in moulds, cool non-homogeneously with refractive indices that increase or diminish from point to point below the surface. The formulæ deduced coincide with ordinary lens formulæ when the variation of refractive index is proportional to the square of the depth from the surface. This appears to be nearly the case in disks of cast glue.—W. Wien, researches on the absorption-phenomena occurring in the diffraction of light. This paper discusses diffraction in relation to the colours of metallic reflection. Incidentally it brings out an additional proof that the vibrations are perpendicular to the so-called plane of polarisation.—H. W. Vogel, on some colour-experiments, and on photography in natural colours. Two solutions, one of chrysanilin, the other of anilin blue, in alcohol, are respectively yellow and blue; but when superposed give red, not green. The violet of the spectrum appears to play a very unimportant part in colour-sensations; methyl-violet, and nearly all the so-called violet pigments and dyes owe their tint to mixtures of red and blue rays, not to rays of spectrum violet. For colour-printing at least six tints are found requisite, and in general sufficient. Hence the author thinks that all requirements of colour-photography would be met by six printings from six blocks produced by photography from plates of bromide emulsion, to which the following six substances have been used as "sensibilisators": *red*, naphthol blue; *orange*, cyanin; *yellow*, eosin; *green*, saffranin; *green-blue*, fluorescein; *blue*, chrysanilin or aurantin. The author further points out that as the actual tint of any colouring-matter is the complementary colour to that absorbed by the colouring-matter itself, it follows that each of the six plates ought to be printed off in the same dye-stuff that has served as photographic "sensibilisator."—P. Volkmann, note on Prof. Quincke's remarks on the determination of capillary constants of liquids.—R. Schultze, on a small improvement in Wiedemann's pyknometer.

No. 6, June.—A. Kundt and E. Blasius, remarks on some researches on the pyro-electricity of crystals. A convenient apparatus for heating crystals is described; also some observations on the amethyst. The effects of cracks in the crystals are also studied.—K. Mack, pyro-electric and optical observations

on Brazilian topaz. The author refers the phenomena to the presence of a single electric axis, inclined to each of the three principal axes of the crystal. He also points out that the two optic axes do not make equal angles with the greatest of the three principal axes.—W. Stscheglajeff, on the electro-magnetic rotation of the plane of polarisation in chloride of iron. Curves given show that in this substance Verdet's rule that the rotation is proportional to the intensity of the field is not observed.—H. Haga, experimental researches on the convection of heat by the electric current. Careful experiments described in this paper show that the Thomson effect in mercury is negative.—Fr. Stenger, on phenomena of fluorescence. Some doubt having been thrown upon the transmutation, by Magdala red and other bodies, of red rays into orange or yellow rays, the appearance of these higher rays being attributed to stray light, the whole matter has been repeated with the utmost precautions. It appears to be now established that eosin and fluorescein also have this property. All three bodies are exceptions to Stokes's rule that the transmutation in fluorescence is always a degradation in the spectrum scale. The author also discusses the matter in relation to Lommel's theory and to the influence of solvents.—E. Ketteler, a remarkable limiting case of crystalline reflection, and its investigation by the aid of the perfected total-reflectomer of Kohlrausch.—G. Hansemann, on a new method of determination of periods of oscillation of bar-magnets. A photographic camera and a mirror oscillating in conjunction with a seconds pendulum are applied to the ordinary apparatus for observing oscillations by reflection.—Werner Siemens, on the conservation of energy in the atmosphere of the earth. A discussion of atmospheric laws and of *vis viva* of the atmospheric masses, too involved for a brief abstract.—R. Gerhardt, on the tube-flute stop of the organ. An experimental and mathematical discussion of the effect of putting a small open tube into the closed top of the flute pipe.—W. Alexejew, on solutions. The author arrives at the following conclusions: solids dissolve better than liquids; at one given temperature a solid can give only one saturated solution, a liquid two; supersaturated solutions have two temperatures of decomposition, one at which decomposition may occur, another at which decomposition must occur. A large number of data of observation are plotted in curves.—E. Himstedt, reply to the observations of Lord Rayleigh upon my determination of the ohm.—L. Graetz, on the dependence of the elasticity of caoutchouc upon temperature, and its relation to coefficients of thermal expansion. From his observations the author predicts that a twisted rod of caoutchouc, when suddenly further twisted, will warm itself.—Fr. Stenger, simple demonstration of residual electric charges, by means of an exhausted tube used as a Leyden jar.—A. Oberbeck, remarks on my work on the resonance of electric oscillations. An acknowledgment of the priority of Dr. J. Hopkinson.—A. König, on an observation respecting the empirical basis of our perception of space. This basis is the apparent extent of the objects in the field of vision as distributed over the retina, and their relative apparent displacement when the eye is turned about.—Fr. Stenger, correction to the memoir on the properties of calc-spar in a homogeneous magnetic field.

Rivista Scientifico-Industriale, June 30.—On some new registering thermic instruments, by Prof. Filippo Artimini. A full description, with illustrations, is given of the author's registering thermo-pyrometer, in which the degrees of temperature are accurately recorded by an ingenious application of electricity.—Telephoning at great distances, by F. van Rysselberghe. The author gives a summary of his recent experiments in the United States, showing the possibility of telephoning at any distance and establishing a regular international telephonic service between all the great cities of the world. The telegraphic wires now in use may be utilised for the simultaneous transmission of telegraphic and telephonic messages.

SOCIETIES AND ACADEMIES

Sydney

Royal Society of New South Wales, June 2.—Chr. Rolleston, C.M.G., President, in the chair.—Papers read:—A new species of Ardisia from New Guinea, by Baron Ferd. von Mueller, K.C.M.G., F.R.S., descriptive of the only specimen as yet found so far north.—A comparison of the dialects of East and West Polynesia, Malay, Malagasy, and Australian, by the Rev. George Pratt, author of a dictionary of the Samoan language. This was a valuable contribution towards a polyglot of the languages of Polynesia, some of which have already passed away, and most of which are changing through the introduction of new words and the rapid intermingling of various races. The Royal Society of New South Wales was urged to take steps to preserve these records and customs not only of Polynesia, but of the fast-diminishing tribes of Australia.—The discovery of a poison in three species of Daphnandra, a genus of plants of the order Monimiaceæ, by T. L. Bancroft, M.B. (Edin.), F.L.S. (Brisbane).—On some new poisonous substances discovered on the Johnstone River, North Queensland, also by Dr. Bancroft. These papers were descriptive of experiments of the therapeutic action on the guinea-pig.—Prof. Liversidge, F.R.S., exhibited and described: (1) a meteorite, the third one known to be found in New South Wales, composed of iron principally, nickel, cobalt, sulphur, phosphorus, and carbon; (2) the matrix of the rock of the tin deposits of Tasmania, in which the cementing material is topaz; (3) a collection of New South Wales silver ores (38 specimens), collected by Mr. McGarvie Smith; (4) shale from the Hawkesbury sandstone showing worm tracks and perforations, the first time noticed in these rocks.—Mr. Lawrence Hargrave exhibited a model illustrating the undulatory motion of serpents, based upon the trichoidal plane, a continuation of similar studies by him on the motion of fishes and the flight of birds.

Microscopical Section.—The following papers were read during the year 1885:—The *Phylloxera vastatrix*, by Dr. Morris, illustrated with specimens of the diseased vine from the neighbourhood of Sydney; and by the same author, Notes on mounting diatoms in highly refractive media.—Specimens of *A. pellucida* were exhibited mounted in piperine, picric acid, chlorides of tin, and thallium, and sulphur in combination with disulphide of arsenic. These slides were exhaustively tested against the American methods, viz. Dr. Chase's metallic silver and realgar, also Prof. Smith's (Geneva, N.Y.) specimen slide. The microscopes and accessories were of the latest make, and the objectives used were homogeneous immersions by Tolles, 1/10, 1/25; Spencer, 1/12; Powell, 1/12, 1/20. The slides of Dr. Morris's sulphur and arsenic combination gave the best results. In addition to the above-mentioned objectives the following choice glasses were acquired by members of the section during the year:—Powell's, 1/6; Hom N.A., 1·5; Green (late Tolles), 1/2″ 30°; Bausch and Lomb's, 1/16 immersion; Wales, 1/12 immersion, 170°. A valuable Ross Zentmeyer binocular stand with apparatus was presented by H. G. Wright, M.R.C.S.E., whilst immersion and high-angled condensers were purchased. Amongst the numerous slides exhibited were some of new mosses found in the neighbourhood of Sydney by Mr. Whitelegge, and a bacillus found by Dr. Morris in the ulcerated intestine of a foal, the cause evidently of a widely spread epidemic prevalent throughout the colony amongst young foals only.

Paris

Academy of Sciences, August 2.—M. Jurien de la Gravière, President, in the chair.—On the relations of geodesy to geology, by M. H. Faye. In this second communication it is shown that the harmony of the two sciences results in the remarkable law determining the constancy of the mathematical figure of the globe throughout the whole series of geological evolutions, a law which sooner or later will enable us to form a clear idea regarding the thickness of the present crust of the earth. At the same time the problem cannot be completely solved by the resources of geometry alone, and recourse must be had to the other sciences bearing on the subject.—On the displacement of ammonia by other bases, and on its quantitative analysis in the soil, by MM. Berthelot and André. From their further researches the authors conclude that magnesia cannot be safely employed for the quantitative analysis of ammonia in the analysis of the earths and other organic products containing insoluble double ammoniacal salts. Certain derivatives from the aldehydes are in the same position, as are also probably the ammoniacal salts formed by the humic and allied acids.—On the quantitative analysis of ammonia (continued), by M. Th. Schlœsing. Having previously shown (July 26) that by distillation on magnesia all the ammonia may be extracted from the solution of its hydrochlorate, or from that of the ammoniaco-magnesian phosphate, the author completes his demonstration by causing the magnesia to act on the double ammoniacal salts, and especially on the chlorides containing magnesium and zinc.—Observations on the oldest sedimentary groups in the north-west of France (continued), by M. Hébert. A careful study of the whole region

leads to the conclusion that North Brittany, north of a line drawn from Quimper to Rennes, and West Normandy, north of a line drawn from Pontorson to Domfront and Falaise, are mainly constituted by the vertical clay-slates of Saint-Lô, overlain by the purple conglomerates, schists, and nearly horizontal red sandstones. Thus is confirmed the general conclusion announced by Dufrénoy in 1835.—On the presence of microscopic mineral crystals of the feldspar group in certain Jurassic limestones of the Alps, by M. Ch. Lory. The crystals here described yield on analysis about 47 per cent. of potassic and sodic feldspar mixed with a little albite; 45 of quartz in bipyramidal crystals and pulverised; 8 of argile, analogous in its composition to that of the carbonates of lime of the same horizon.—On the operations prosecuted in Tunisia by Commander Landas since the death of Col. Roudaire, by M. de Lesseps. The creation of an inland sea, the original object of these works, has been definitively abandoned, and attention is now devoted to the Wed Melah basin, which, by the sinking of Artesian wells, promises soon to recover its former productiveness.—Note on M. Marcel Deprez's experiments relating to the transmission of force between Creil and Paris, by M. Maurice Lévy. In this note is embodied the report of the sub-committee appointed to verify the results already obtained by M. Deprez during the course of the experiments carried out by him at Creil since November 1885. The main object of these experiments was to show the possibility of transmitting electrically to the Paris terminus, a distance of 56 kilometres, a force of 200 horse-power generated at Creil on the Great Northern line, with an effective yield of 50 per cent. The preliminary operations, concluded on May 24, show that the force consumed at Creil varied from 67 to 116 horse-power, that received at Paris from 27 to 52 horse-power, the yield being from about 41 to 45 per cent., and increasing with the transmitted force. The experiments, conducted at the expense of MM. Rothschild, show conclusively that with a single generator and a single receiver force may be profitably transmitted to a distance of over thirty miles with a loss of not more than 55 per cent. on 52 horse-power, without exceeding a current of 10 amperes, an angular velocity of 216 revolutions per minute, or a peripheric velocity of 7·50 m. per second. With improved appliances the loss, mainly due to absorption by the machines themselves, will probably be reduced to 50 per cent., and to still less in operations conducted on a larger scale.—Measurement of the intensity of sound by means of the manometric flames, by M. E. Doumer. It is shown that this apparatus, hitherto used mainly as a method of demonstration and summary study of the *timbre* of vocal sounds, is susceptible of far more varied applications, and especially may rival the graphic method in determining the height or intensity of sound.—On the separation of arsenic, antimony, and tin, by M. Ad. Carnot. By employing oxalic acid and the hyposulphite of soda or ammonia, sulphurous acid and sulphuretted hydrogen, the author has succeeded in effecting these separations rapidly and accurately, as he had already effected the separation of copper, cadmium, zinc, and nickel. His new methods enable him greatly to simplify the analysis of the complex alloys, of which these metals are constituents.—Heat of formation of the crystallised seleniures and of the amorphous seleniures, by M. Charles Fabre. Here are treated the seleniures of iron, manganese, cobalt, nickel, zinc, cadmium, copper, thallium, lead, mercury, and silver. In general the heat of formation of the seleniures prepared at high temperatures is shown to be equal or slightly inferior to that of the corresponding precipitated sulphides.—On the combinations of chloral and of resorcine, by M. H. Causse.—On the composition of the element in the grease of sheep's wool which is soluble in water, by M. E. Maumené.—On the indirect innervation of the skin, by M. C. Vanlair.—Note on the arterial system of the scorpion, by M. F. Houssay.—Fresh researches on the production of monstrosities in the hen's egg by a modification of the germ before incubation, by M. Dareste.—Observations on the pollinisation of orchids indigenous in France, by M. Paul Maury.—A first survey of the vegetation in the French territory of the Congo, by M. Ed. Bureau. The botanical collections formed by the Mission of West Africa, which have already reached Paris, comprise two herbariums, one collected by MM. Thollon and Schwéhisch, the other by MM. J. de Brazza and Pecile. There are altogether 599 species, chiefly from the districts of Franceville, Brazzaville, Ossika, Diélé, Lékéti, and Nganshu, on the Ogoway, Alima, and Lower Congo.

BERLIN

Chemical Society, May 24.—Dr. W. Will reported on the utilisation of myristic acid for lauric acid. According to the investigations of C. Reimer and W. Will there was, in the nuts of *Myristica surinamensis*, an excellent material for obtaining large quantities of myristic acid. Herr Lutz, student, had obtained from it myristinamid, and in accordance with the method of Hofmann, had transferred that into myristintridecyl-urea, tridecylamin, tridecyl nitrite, tridecylamid, and the corresponding combinations of the twelfth series, inclusive of lauric acid.—Herr O. N. Witt reported on experiments for the local determination of the sulfo group in the naphthalic acids, which led him to the same results as those obtained by Clève.—Prof. C. Liebermann referred to a work undertaken but not yet completed, with a view to the elucidation of the constitution of opianic acid. He showed that there were reasons to support the assumption of an aldehyde group in this compound, as also for the opposite assumption, a fact which led to a discussion on the so-called atom migrations, in which Herren Hofmann, Klason, Liebermann, Krämer, Pinner, and Will took part. Prof. Hofmann then called attention to the fact that such molecular shiftings of place had been particularly in quite recent times observed by him whilst studying the ether of cyanuric acid. He described the formation of a 2/3 iso- and 1/3 ortho-ethyl ether of cyanuric acid which he had obtained from cyanurate of silver by means of ethyliodide. This ether transformed itself, even at the ordinary temperature, into isotriethyl-cyanurate.—In conclusion Prof. Tiemann communicated a work by N. Nagai, on an aromatic ketone isolated from the root of a Japanese peony, having the constitution—

$$C_6H_3(OCH_3)(OH)(COCH_3).$$

BOOKS AND PAMPHLETS RECEIVED

"Madagaskar," by Prof. R. Hartman (Freytag, Leipzig).—"Elements of the Comparative Anatomy of Vertebrates," by R. Wiedersheim; translated by W. N. Parker (Macmillan).—"Bulletin de la Société Impériale des Naturalistes de Moscou," No. 1, 1886 (Moscou).—"Publications of the Leander McCormick Observatory, Virginia," vol. i. part 2.—"Algebra," part 1, by G. Chrystal (Black, Edinburgh).—"The Gold Fields of Victoria: Reports of the Mining Registrars for the Quarter ended March 31, 1886" (Ferres, Melbourne).—"Science and Art Directory," revised to July 1886.

THURSDAY, AUGUST 19, 1886

PHYSICAL HYPOTHESES

Le Ipotesi Fisiche. Analizzate da Giannantonio Zanon. (Venezia: Lorenzo Tondelli, 1885.)

AT its sitting of July 17, 1881, the Royal Venetian Institute of Sciences proposed as the subject of a prize an examination of recent hypotheses regarding the causes of luminous, thermal, electrical, and magnetic phenomena. The volume now before us is one of seven competing treatises produced by the end of March 1883. As to the vastness of its scope, and the extent of erudition displayed in it, we can fully ratify the sentence of the examiners officially deputed to pronounce upon its merits. It is an "attack all along the line," and one conducted with no despicable array of mustered forces. The author has read and pondered much on the subjects he treats of; he is a mathematician, and is hence alive no less to the value of mathematical evidence, than to the worthlessness of a mere hollow show of mathematical formulæ; while the hypotheses he criticises have usually been tried by the severe test of a serious endeavour to realise their consequences. Many of his objections we at once admit to be valid; indeed, no universal explanation of physical phenomena has yet been proposed of which the structure was not riddled with visible absurdities. The late Prof. Challis devoted his considerable abilities and his best energies to the elaboration of a hydrodynamical theory of the universe, in which physical effects of all kinds were referred to forms of pressure of a continuous elastic medium. But the suggestion that an indefinite ascending series of such media might, after all, be necessary to produce the required results, cannot be looked upon otherwise than as a confession of failure. Father Secchi's heroic effort, in his "Unità delle Forze Fisiche," to see right down to the very bottom of things, was scarcely more successful. The reasonings upon which it was founded (as our author, among others, rightly points out) were vitiated at the root by a misapplication of Poinsot's theorems on the resilience of rotating bodies; and the cosmical machinery put together with such ingenuity, and set going with such heedful solicitude, came at once to a deadlock. Nor do we anticipate any better results from the scheme which Prof. Zanon himself promises to expound in a forthcoming work. The glimpses of his views afforded in essays already before the public are not encouraging. There is absolutely nothing gained in devolving the responsibility of our ignorance upon phrases, and taking their obscurity for illumination. If we can find no adequate explanation of the activities manifested in the wonderful "frame of things," of which we are at once spectators and participators, let us, in the name of candour and common-sense, acknowledge our impotence; but let us not imagine that we in any sense repair or qualify it by talking of inherent qualities, "virtues," propagated "influences," "molecular tensions," and the like. This would be to fall back into the rut out of which Molière did something to help us with Argan's famous diploma-examination:—

"Mihi a docto doctore
Domandatur causam et rationem quare
Opium facit dormire.
A quoi respondeo,
Quia est in eo
Virtus dormitiva,
Cujus est natura
Sensus assoupire."

Undeniable; but uninstructive.

The work we are at present concerned with is divided into an historical and a critical section. Of hypotheses as to the constitution of matter and the causes of physical action, the human mind has in all ages been prolific. Their procession, lengthy as that which defiled before Bradamante in the grotto of Merlin, is here carefully, and as expeditiously as may be, marshalled for our benefit. From the aqueous world of Thales to the vortex-atom world of Sir William Thomson, we are enabled to trace the progress, or rather the vicissitudes, of thought. For it is not in this field that the amazing advances of modern science have been made. The subject of Prof. Zanon's sketch is, not the onward march of natural investigation, but the "stations and retrogradations" of speculative physics. More than once, indeed, he is forced to exclaim with Horace, "Multa renascentur, quæ jam cecidere." The incidental inclusion of some fragments of genuine scientific theory, legitimately verified by experience, does not alter this general character.

The narrative is disfigured by a few inadvertencies. At p. 44, for example, the origination of the wave-theory of light is ascribed to Malebranche; but in the very next page, and with better reason, to Hooke, whose "Micrographia," containing the assertion that "light is a very short vibrative motion," propagated in spherical waves of agitation through "an homogeneous medium," appeared in 1665, nine years before the first-fruits of Malebranche's meditations were given to the world. At p. 50, Lavoisier's *rationale* of combustion is inextricably involved with his *rationale* of the decomposition of water; and at p. 118 the point is strangely missed of Prof. Tyndall's illustrative explanation of the change from the liquid to the gaseous state. It is worth while to point out these slips in a book representing a large amount of painstaking original research.

No notice is taken in it of Isenkrahe's recent speculations concerning the cause of gravity. They belong to the same family with those of Le Sage, justly condemned as "a mere effort of imagination, defiant alike of the dictates of reason and the laws of nature" (p. 229). Shelter from molecular bombardment, in one form or the other, is the key offered by them to the standing riddle of the cosmos. They explain gravity as a *push*, not a *pull*. Central forces are replaced by the preponderant external impacts of "mundane" or "ultramundane" particles. Such theories write their own sentence. They include their own condemnation. For, as M. Isenkrahe with the utmost candour points out, the very form of his fundamental equation implies a contradiction of the law that gravity varies with mass. It is obeyed only when the value of the equation becomes equal to nothing—that is, when there is no action of the kind postulated.

In the critical section of Prof. Zanon's volume, theories of the constitution of matter are examined separately from theories of the physical forces. That perplexities

exist in both departments of research is a statement equivalent to the as yet undisputed assertion that human faculties are limited and human knowledge imperfect. Nevertheless, some of the difficulties raised by him are well worthy of thoughtful consideration. There can be no doubt, for instance, that the results of M. Gustav Hirn's experiments on the resistance to motion of air at different temperatures are gravely embarrassing to the kinetic theory of gases. The resistance *ought* to vary as the square root of the absolute temperature; it continues, nevertheless, practically unchanged at all temperatures, so long as the density remains the same (*Comptes Rendus*, t. xciv. p. 379).

Our author's strictures, however, although couched in terms of praiseworthy moderation and fairness, are somewhat too indiscriminate. His respect for thoroughgoing scientific work is evident and unfeigned; but it is almost impossible to take up the position of a sceptic *ex professo*, without at times incurring the reproach of perversity. We are totally unable to see the force of his reasons for preferring the obscure notion of a threefold spectrum containing chemical rays specifically distinct from thermal, and thermal from luminous, to the simple and intelligible view which substitutes for intangible differences of quality in radiations, measurable differences of wave-length. Nor can we believe that he would, on mature consideration, attempt to maintain the opinion that the planetary movements would remain unaffected by the progressive transmission of gravity. It is demonstrable that a species of aberration would thence ensue involving accelerative effects the insensibility of which so far proves (as Laplace has shown) that gravitative influence travels *at least* fifty million times faster than light. We owe the remark to Mr. William B. Taylor (*Smithsonian Report*, 1876, p. 212), that if one minute were spent on the journey from the sun to the earth, the consequent slight obliquity of traction, represented by an angle of 2″·4, would produce a shortening of the year perceptible while the sun was finishing a single round of the Signs.

Prof. Zanon appears to have bestowed much intelligent study on spectroscopic science. He carefully examines Mr. Lockyer's discovery of the independent "behaviour" of iron lines (amongst others) in spots and prominences, and though rejecting the inference of dissociation, he admits the necessity of assuming an *ad libitum* number of allotropic forms of the substance in question in order to explain anomalous appearances. He published moreover in 1880 a detailed analysis of Mr. Lockyer's "Studies in Spectrum Analysis," deriving therefrom confirmation in many particulars of his own views as to the nature of matter. Whatever we may think of these, there can be no doubt that our hope of penetrating the mysteries of molecular constitution must in future rest on the disclosures of the spectroscope. We do not in the least believe that these point towards the conclusion deprecated by Prof. Zanon of a fundamental unity of substance. On the contrary, Mr. Lockyer's striking observations indicate (if we may be allowed the expression) divergent, rather than convergent, simplifications.

It is perhaps inevitable in a work of the character of that now under consideration that the value to science of "working hypotheses" should be taken little account of. Yet the story of man's progressive knowledge of nature is a story of tentative efforts to represent facts to thought. Without some method of provisionally co-ordinating phenomena, indeed, the advance from a lower to a higher stage of induction, which we call discovery, could scarcely at all be effected. The true investigator is he who is never weary of collecting particulars to fit into his framework of theory, and of reconstructing his framework of theory to match fresh particulars. Without the power of thinking appearances into shape, no diligence in amassing the details of those appearances is of the slightest avail.

There is, it is true, the danger of a working hypothesis hardening unduly or prematurely into a theory—of a mere track, struck out for surveying purposes, turning into a fenced highway, without exit save in a quagmire. Against this peril the activity of such critics as Prof. Zanon is a very effectual safeguard. Their assaults may sometimes appear vexatious, but are really directed in the best interests of science, as hindering false security, and leading to a juster estimate of probabilities.

A. M. CLERKE

A MANUAL OF MECHANICS

A Manual of Mechanics; an Elementary Text-Book, designed for Students of Applied Mechanics. By T. M. Goodeve, M.A. (London: Longmans, 1886.)

THIS little work is evidently meant for readers whose knowledge of mathematics is small. The amount of mathematical knowledge supposed may, perhaps, be best inferred from an example quoted from the book itself. In p. 32 we have the problem to find the resultant of two equal rectangular forces, P. If R is the resultant, $R = P\sqrt{2}$. "Now $\sqrt{2} = \sqrt{\frac{50}{25}} = \sqrt{\frac{49}{25}}$ very nearly; ∴ $\sqrt{2} = \frac{7}{5}$ very nearly. Whence $R = \frac{7}{5}P$." When the angle between the lines of action of the forces is 120°, R should be equal to P; but it is proved in p. 33 to be equal to $P\sqrt{3}$, by an unaccountable error in the application of an elementary formula. However, $\sqrt{3}$ is found by the same process as before. Thus $\sqrt{3} = \sqrt{\frac{48}{16}} = \sqrt{\frac{49}{16}}$, very nearly, $= \frac{7}{4}$.

Now what naturally strikes one about beginners who have to be spoon-fed in this fashion is that it would be very much better to spend some time in teaching them trigonometry and algebra, than to push them into dynamics with the very slender knowledge of arithmetic and geometry which they possess. In our system of national education there is far too much effort employed in bringing branches of dynamics and physics *down* to the level of the ignorant, and too little in bringing students *up* to the standard of mathematical attainment required for a really intelligent knowledge of these subjects. The result of this system is that nearly all our elementary scientific books are very scrappy in character, presenting to their readers conceptions which they cannot possibly realise, and which must therefore be crammed into the mind as mere definitions devoid of real meaning.

In elementary scientific treatises it is necessary to insist, above all things, that the information given to the

reader shall be above reproach, so that if he further pursues the subject treated of, he may, at least, not be hindered or misled by erroneous definitions or ideas placed before him at the outset.

The work before us, when it has been subjected to a slight revision, will fairly satisfy the conditions of an elementary text-book which is at once strictly scientific in its ideas and rich in practical applications.

Indeed, the practical portion of the work is, as was to be expected, very good. The portions dealing with mechanism are well suited to illustrate the scientific principles, and will be found very useful.

We shall confine ourselves to pointing out some of the blemishes which disfigure the theoretical portion.

P. 1. "When the tendency which force exerts to move a body is counteracted, so that the body remains at rest, the force is commonly called a *pressure*." It may be safely said that no such limited use is ordinarily made of the term *pressure*.

P. 2. The statement that two lumps of sugar placed in contact on a table do not adhere, because "the attraction emanates from their centres, which may be an inch apart," is not altogether conducive to sound notions.

In p. 19 we have the usual definition of the measure of a variable velocity, viz. "the space which would be described in a unit of time if the body retained throughout that unit the velocity which it has at the instant considered." When will people find out that this definition really defines nothing? It is truly Gladstonian in its elusiveness. Of course we find exactly the same "definition" of variable angular velocity (p. 62), variable acceleration (p. 99), and variable pressure (p. 176).

In p. 26 we have a most confusing exposition of Newton's Second Law. What, for instance, is the beginner to understand by this?—"Since we are dealing with a body in motion, it is clear that we may consider (1) the weight of the body to be constant, and its velocity to vary; (2) the weight of the body to vary, and its velocity to remain constant." The discussion of this law seems to show that its object is entirely misconceived by the author. For, while the law aims at giving a complete measure of *force*, the author merely *deduces from it* (by reasoning in a circle) a definition of momentum, his discussion ending with the words, "Hence, quantity of motion = (mass) (velocity)."

Again, in p. 28, "the explosive force of powder in a gun is *action*, and the momentum generated in the projectile is *reaction*." This is plainly open to the objection of equating force to momentum—a most mischievous notion.

In p. 48 the full meaning of the *centre of parallel forces* is by no means brought out, and the rule for finding its distance from a given line is incorrect: "Multiply each force into its perpendicular distance from a given line," &c. The rule ought to be enunciated with reference to a *plane*, and not to a *line*, and instead of the unmeaning term "distance of a force from the plane" we should say "distance of its point of application from the plane."

It is surely incorrect to say, as in p. 61, that "it is the universal practice to appropriate the Greek letter ω (omega) for expressing the unit of angular velocity."

It is very important to distinguish, in the mind of the beginner, between *force* and *power*. In p. 72 power is correctly defined as [time-] rate of doing work; but the language immediately following loosens this idea. Thus, "the number 33,000 foot-pounds is the *unit* of horse-power." There is tautology in the expression "Watt estimated that the sustained work of a horse continued for one minute would raise 33 000 lbs. through one foot in one minute." Again, the term *power* is used in p. 94 to designate a force applied to a machine.

In p. 73 the principle of work as applied to equilibrium is thus enunciated: "If a system of bodies be at rest under the action of any forces, and be moved a very little, no work will be done." It may well be doubted whether this enunciation is explicit enough to give a useful idea of the great statical principle. Indeed, the cases selected for illustration bear out in no way the proviso that the bodies must "be moved a very little."

Passing on to p. 98, we find acceleration of velocity discussed, and we have the formal definition: "the unit of acceleration adds a velocity of 1 foot in 1 second," which, as the words stand, has absolutely no meaning. The beginner ought to be taught that acceleration has a double reference to time, and it should never for a moment be spoken of otherwise than as "feet per second per second," or "miles per hour per minute," or by some other equivalent phrase. In p. 102, g is spoken of as 32·2 feet per second.

Finally, in p. 113 the beginner is introduced to the discussion of a compound pendulum formed by a straight uniform bar. Its time of oscillation depends on a radius of gyration. What idea is our beginner likely to have of this? The definition of k, the radius of gyration of the bar AB about an axis through its centre of gravity, G (p. 114), is quite erroneous—"let k^2 be the sum of the squares of the distances of each particle of AB from the point G." This sum is, of course, infinite. What is meant by k^2 is the *mean* square of distance from G. But clearly such a question is wholly unsuited to beginners.

The book concludes with a large collection of examples, taken from the Science Examinations, which will be useful to students. GEORGE M. MINCHIN

OUR BOOK SHELF

Mémoire sur les Volumes moléculaires des Liquides, avec un Avant-propos. By Hermann Kopp. Pp. 47. (Heidelberg: C. Winter, 1886.)

THIS is a *brochure* one-third of which is devoted to an "avant-propos" explaining why the paper does not appear in the *Annales de Chimie et Physique*, and making certain statements relating to M. Berthelot's recent work, "Les Origines de l'Alchimie." The remaining part contains a discussion of a paper on molecular volumes of liquids which appeared in the *Annales*. In 1869 Prof. Kopp published, in succession to his "Geschichte der Chemie," a volume of "Beiträge" to the history, explaining more fully the principal epochs in chemical history, more especially in relation to alchemy. In 1885 M. Berthelot published his work, which had occupied more or less of his attention since 1869. Its general character is very similar to the "Beiträge," though much less complete, and Kopp complains that no reference whatever is made to his book. Berthelot, in reply, states that he was unaware of the existence of the "Beiträge," yet he quotes references to works in which this "cahier" (as he calls it) is repeatedly mentioned. The oversight is a very grave one, when we remember that the "cahier" is a contribution of over

800 pages, and when we consider the position which Prof. Kopp holds as an historian of chemistry, a position which demands that due regard should be paid to his writings.

The more immediate object of the pamphlet is, however, to reply to the strictures of MM. Bartoli and Stracciati on the law of molecular volumes. These gentlemen have criticised somewhat severely Kopp's work in this department without taking into consideration the obstacles which, at the time it was carried out (1855) stood in the way of accurate and definite investigation. Singularly enough, they do not escape the same charge, having themselves in some cases made use of materials of an insufficient degree of purity. It is likewise pointed out that they are labouring under a complete misapprehension of the views held by Kopp and the significance of his deductions, nor do they seem to have appreciated the difficulties that surround the establishment of a "physical law" of general application. G. H. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Organic Evolution

ALLUDING to the first instalment of your abstract of my recently published paper on "Physiological Selection," the Duke of Argyll remarks :—

"I rejoice that the author has at last discovered that 'natural selection has been made to pose as a theory of the origin of species, whereas in point of fact it is nothing of the kind.' This has been my contention for many years" (NATURE, vol. xxxiv. p. 335).

These words seem to imply that my views with regard to natural selection have now undergone an important change, and one which brings them into conformity with those that have for many years been contended for by the Duke. It therefore seems desirable to state that such is not the case; and as I can only attribute the misunderstanding of so able and friendly a reader to some ambiguity in the condensed abstract of my paper to which he refers, I may invite him to consult the paper itself, where the matter to which he alludes is more fully explained. He will there find that my views upon the subject of natural selection are the same now as they have been during the last fifteen years; that in all essential respects they still coincide with those that were held by Mr. Darwin; and that my "additional suggestion on the origin of species, although quite independent of natural selection, is in no way opposed to natural selection," but is to be regarded as indicating "a factor supplementary to natural selection."

The state of matters, then, is simply this. Mr. Darwin himself has freely acknowledged that his theory of natural selection is not in itself a sufficient explanation of the origin of species. He therefore supplemented the natural causes which are together comprised under this term [1] by sundry other causes of a similarly natural kind. Of these he attributed most importance to use, disuse, sexual selection, correlated variation, and prolonged exposure to uniform conditions of life. To these supplementary causes Moritz Wagner added independent variation in the absence of intercrossing with parent forms, while I have myself added physiological selection. Now, the whole body of Mr. Darwin's followers have agreed with him in holding that the theory of natural selection is not in itself a sufficient explanation of the origin of species. But many of these followers differ from Mr. Darwin, and also differ among themselves, as to the proportional part which the principle of natural selection is to be considered as having played in the evolution of species. Mr. Darwin thought that in this respect natural selection plays a more important part than any other principle [therefore it is hard to see how in this respect any of "the successors of Darwin" can possibly "have run quite wild from the teaching of their master"], while in the opinion of many of his followers this principle should be regarded as of a value subordinate to the others. Of all the writers who have taken the latter view, the most clear-headed, as well as the earliest and most persistent, is Mr. Herbert Spencer. He more than any other author has been instant, both in season and out of season, in giving reasons for the scepticism that is in him. I confess, therefore, to not understanding the Duke of Argyll when he says that in the two articles recently published by Mr. Spencer "we have for the first time an avowed and definite declaration against some of the leading ideas on which the Mechanical Philosophy depends." So far as I can see, these two articles convey little more than a reiteration of the characteristically Spencerian view that, in the course of organic evolution the processes of "direct equilibration" have been of more importance than those of "indirect equilibration." By the first of these terms Mr. Spencer means use, disuse, and all other causes tending directly to the production of adaptive structures, while by the second he means natural selection. Now, from the time when Mr. Darwin first published his "Origin of Species" the main point of difference between his views and those of Mr. Spencer has uniformly consisted in the estimates which they have formed of the relative importance of these two kinds of equilibration. Surely, therefore, this cannot be the respect in which it is said that Mr. Spencer has "now for the first time opened his eyes and his mouth." Yet, if not, I do not understand the allusion. The Duke seems to imagine that, in some way or another, Mr. Spencer has taken a new and important "point of departure" in the course of his speculative thinking, and one which is "fatal to the adequacy of the Mechanical Philosophy as any explanation of organic evolution." It would be a matter of great interest to me—and I am sure to many others who have read the articles in question—to be told in what respect Mr. Spencer has committed himself to so great a change of doctrine; and it would certainly be a matter of profound astonishment to all evolutionists if Mr. Spencer can be shown to have so much as insinuated that his "direct equilibration" differs from Mr. Darwin's natural selection in not belonging to the system of so-called Mechanical Philosophy—or that those factors of organic evolution on which he has mainly relied differ from those on which Mr. Darwin has mainly relied in lending better countenance to the Supernatural Philosophy of Design.

My own attitude with regard to all these questions is perfectly plain and simple. In common with Darwin, Spencer, and the great majority of evolutionists, I believe that in the origin and development of adaptations—whether structural or instinctive—two sets of strictly natural causes have been at work: I agree with Mr. Darwin in thinking that of these two sets of causes the "indirectly equilibrating" have been of more importance than the "directly equilibrating": but I differ from other evolutionists, both of the Darwinian and Spencerian schools, in expressly drawing a marked distinction between causes of either kind which have been operative in the evolution of *adaptations* and those which have been operative in the evolution of *species*; and, lastly, I claim to have shown that when once this distinction is recognised, the theory of natural selection ceases to be, properly speaking, a theory of the origin of species; that it is thus liberated from all the difficulties with which it has hitherto been entangled on account of its having been made to "pose" as such; and that it is therefore placed in a position of greater

[1] In common with many other critics of Mr. Darwin's work, the Duke of Argyll has always contended that the theory of natural selection is "fundamentally erroneous" in that it assumes "variations to arise by accident," and merely "groups under one form of words, highly charged with metaphor, an immense variety of causes, some purely mental, some purely vital, and others purely physical or mechanical." This, however, is no valid criticism of the theory, which for the first time did comprise under one general point of view all the causes which together go to produce the results. In the opinion of the Duke, the weakest element of the theory consists in its inability to explain the causes of those variations on the occurrence of which the theory depends (NATURE, *loc. cit.*, p. 336). But it is clearly no valid objection to a theory which explains one set of causes that it is unable to explain another and ulterior set. So long as variations of all kinds are known to be matters of fact, they are available for the theory of natural selection, even though the ulterior or physiological causes of variation should never be discovered. And for all the purposes of this theory it makes no difference whether the variations which are seen to take place in all directions, *with and without respect to utility*, are spoken of as "accidental" or as due to hidden causes. All that this theory has to do is to take the principle of promiscuous variation in all directions as a datum supplied by observation, and from this fact to show how the further principles of heredity, struggle, and survival are competent to *select* the variations which happen to be useful from those which are not. One might as well object to the physical explanation of specific gravity in selecting or sorting the different materials of a sea-shore, on the ground that we do not know the causes either of gravity in general or of the variations that are observable among specific gravities in particular.

logical security than it has ever occupied before. Far, then, from joining the "contention" of my critic in seeking to depose natural selection as a theory of the genesis of adaptive structures and instincts, I have expressly sought to fortify that theory as a "mechanical" explanation of these phenomena. Whether or not I have been successful I must leave others to judge, *after they have done me the justice to read my original paper.* But, be this as it may, the ambiguity of that paper must indeed be extraordinary, if it leads any one to suppose that my argument is precisely the opposite of what it is intended to be.

Geanies, Ross-shire, August 16 GEORGE J. ROMANES

Meteorology and Colliery Explosions

THE catastrophe at Woodend Colliery on Friday last again directs attention to the connection generally believed to exist between explosions of fire-damp and atmospheric changes. The real nature of this connection is but little, if at all, understood. From time to time observations have been taken with the view of throwing some light on the subject, but as the observations in one mine were discussed without reference to what may have been occurring in other districts, the results have not added much to our knowledge. Meteorology, however, is now sufficiently advanced to permit the adoption of another and more satisfactory method of dealing with the question.

The idea so long prevalent that certain fixed points on the barometric scale indicated certain kinds of weather has now been discarded, the examination of synchronous weather charts showing conclusively that the weather changes are not so much dependent upon the height of the barometer at any one place as upon the relations existing between readings over a tract of country; the direction in which the highest and lowest readings lie, and the difference of pressure (the barometric gradient) between neighbouring places—these form the basis of our modern weather knowledge. Nothing of this kind has hitherto been attempted when dealing with observations from collieries. If the presence of gas in mines is in any way regulated by changes of atmospheric pressure, it would be well to see if, like the weather, it is distributed in areas, and whether in these areas again some localities would have more gas than others, dependent more upon the distribution of pressure than upon local readings. With the object of discovering some law or laws governing the presence of gas, I appeal to colliery officials in every coal-field in Great Britain and Ireland to supply me with the few observations detailed below for a period of four months—from September 1 to December 31, the best part of the year for such work.

The Meteorological Office Weather Charts issued daily (Sundays included) at 8 a.m. and 6 p.m. show the distribution of pressure, winds, temperature, and weather. To these I propose adding the information supplied from mines *at the same hours.* Those who cannot arrange for two observations daily, to give preference to the morning set. The gas observation being the most important, I would be glad if precise information can be given. Absolute uniformity cannot be expected, but I would suggest that, where possible, a disused gallery favourable to the object in view should be used, one where the changes in the quantity of gas can be stated in yards or feet, thus turning the gallery into a gas barometer somewhat similar to the one at Seaham Colliery after the explosion of a few years ago. Those who have not the facilities for such measurements can still give valuable data if they do no more than note the increase or decrease of gas as "slight," "moderate," or "great." The appended specimen of the form for recording the observations

Form for Recording Observations

.... Colliery, near ... .

Date, September 1886	Top of shaft, ... feet above sea-level		In underground workings, ... yards from shaft ...... feet below pit-bank			Gas in gallery, yards	Remarks
	Temperature in the shade	Weather	Barometer	Temperature	Quantity of air passing

Railway Weather Signals

WITH reference to the notice given in NATURE, vol. xxxiv. p. 347, of the ingenious plan adopted by the Norwegian Meteorological Institute for disseminating its weather reports, it may not be known to all of your readers that a similar system of signals has been in use for some time on the railroads in Ohio, Pennsylvania, and Canada. The day signals there consist of sheet-iron disks about three feet in diameter, and are displayed on the side of baggage-cars. The signals are shaped like the sun, a crescent, or a star, and differ in colour, being red or blue. The red colour refers to the temperature, and the blue to the state of the weather, as rainfall or snow. This system of signals was first brought into practical operation by Prof. T. C. Mendenhall, Chief of the Ohio Meteorological Bureau.

A system of night-signals for railways is also under trial in Pennsylvania: they are in the form of rockets or an exploding cartridge, which, when fired, may be seen from six to ten miles. CHAS. HARDING

August 17

Tornaria and Actinotrocha of the British Coasts

THREE species of Balanoglossus are known to occur on the shores of North-West Europe. *Balanoglossus kupfferi* was taken by Willemoes Suhm at Helleback, in the Sound, that is, on the coast of Zealand (*Zeit. f. wiss. Zool.* vol. xxi. 1871); *Balanoglossus salmoneus*, Giard, and *B. robinii* occur, according to Mr. Bateson's last paper in the *Quarterly Journal of Microscopical Science*, at Concarneau, in Finistère, and I believe also at the Channel Islands. But no Balanoglossus has yet been found on the shores of Britain. It will therefore be of some interest to British naturalists to learn that in August 1884 I obtained in the tow-net a larva which seemed to possess the distinctive characters of Tornaria. I had not leisure at the time to study the specimen with much attention, but I made a hurried sketch of it, which shows the presence of two parallel longitudinal bands of cilia anteriorly, and a single transverse band posteriorly. At the posterior end is a conical protuberance resembling the adhesive organ described by Bateson in his creeping larva. The position of the mouth was not ascertained, but was probably between the two anterior bands of cilia. The water vessel and tuft of cilia at the apex of the præoral lobe were not observed. This larva may not have been Tornaria, but I think it really was that form; and naturalists who are spending an autumn holiday at the sea-side would probably, if they undertook the search, succeed in finding Balanoglossus in the littoral sands, and its larvæ in the shore waters.

Phorenis is also at present, I believe, excluded from the British littoral fauna, but is certainly present on our shores, though no adult specimens have been taken. I took large numbers of Actinotrocha in the tow-net, close to the shore, in September 1883, a little to the north of the mouth of the Cromarty Firth. If I am mistaken in supposing that adult Phorenis and Balanoglossus have never been found on the coast of Britain, I shall be glad to be corrected. J. T. CUNNINGHAM

Mock Suns

As I observe the omission from my letter on the parhelia or mock suns of last month (p. 313) of the diagram which was

intended to describe the real phenomena, may I ask you to allow me a few lines of space for the following :—

The real sun was surrounded at a short distance by a halo or rainbow circle of great beauty, with a mock sun of the same apparent magnitude and brightness on the right and left ; and *partially* formed suns above and below the ring : all of them being slightly opalescent. From the two perfected suns proceeded cones of intense light, about 3 diameters of the sun in length, and with their apices pointing east and west. These were rather more opalescent than the mock suns from which they seemed to originate. A second rainbow ring at a considerable distance outside of these extended to the zenith. The period of greatest beauty and brightness, when they were as rich in colouring as a real rainbow, lasted about 5 minutes. I was able to watch the whole of the phenomena from a little after 4 to nearly 6 o'clock.

Jasper Road, Upper Norwood

PHYSIOLOGICAL SELECTION: AN ADDITIONAL SUGGESTION ON THE ORIGIN OF SPECIES[1]

III.

Argument from the Prevention of Intercrossing.—This argument is the same from whatever cause the prevention of intercrossing may arise. Where intercrossing is prevented by geographical barriers or by migration, it is more easy to prove the evolution of new species as a consequence than it is when intercrossing is prevented by physiological barriers ; for in the latter case the older and the newer forms will probably continue to occupy the same area, and then there will be no independent evidence to show that the severance between them was due to the prevention of intercrossing. Nevertheless, all the evidence I have of the large part that geographical barriers have played in the evolution of species by preventing intercrossing with parent forms goes to show the probable importance of physiological barriers when acting in the same way. Hence it will be better to postpone this line of argument in favour of physiological selection until the appearance of my next paper, where I shall hope to show, from evidence furnished by the geographical distribution of species, how predominant a part the prevention of intercrossing has played in the evolution of species. Here, therefore, I will merely remark that wherever intercrossing with parent forms is prevented, in the proportion that it is prevented a better opportunity is given to natural selection for seizing upon any beneficial variations that may happen to arise. On this account physiological selection probably lends important aid to natural selection, thus becoming indirectly instrumental in the evolution of useful as well as of useless structures.

There is also another respect in which these two kinds of selection probably co-operate. For Mr. Darwin shows that "it would be clearly advantageous to two varieties, or incipient species, if they could be kept from blending, on the same principle that, when man is selecting at the same time two varieties, it is necessary that he should keep them separate." But he proceeds to show that this advantage cannot be conferred by natural selection, and hence that the sterility which is so generally characteristic of species cannot be attributed to this agency. We have, however, just seen that this sterility is in all likelihood due to physiological selection ; and therefore, if it be true, as Mr. Darwin thought, that "it would profit an incipient species if it were rendered in some slight degree sterile with its parent form," physiological selection and natural selection may mutually assist one another. For, although the benefit of this sterility could not have been initially conferred by natural selection, yet when it once arises from an independent variation in the reproductive system, there is no reason why it should not forthwith be favoured by natural selection, just as is the case with advantageous variations in general.

Feeling how grave a difficulty was presented to his theory of the origin of species by the general sterility of species, Mr. Darwin was extremely anxious to find some way in which natural selection might be seen to have brought about this result. Had it occurred to him that this result was probably nothing more than the necessary expression of a particular kind of variation on the part of the reproductive system, I cannot doubt that he would have felt the theory of natural selection to have been relieved of one of its greatest disabilities.

Argument from the Inutility of Specific Differences.—After what has already been said on this subject, I will here only deal with one question, namely, Why is it that apparently useless structures occur in such profusion among species, in much less profusion among genera, and scarcely at all among families, orders, and classes? It may be answered that the points wherein species differ from species are usually points of smaller detail than those which distinguish genera, families, &c., and thus may well actually be as a rule less useful, although still not absolutely useless : natural selection, it may be urged, is better able than is the naturalist to diagnose utility. But here again we have a most unwarranted appeal to the argument from ignorance ; whereas, according to my view, it is quite intelligible that when a varietal form is differentiated from its parent form by the bar of sterility, isolation, or migration, any little meaningless peculiarities of structure (or of instinct[1]) should at first be allowed to arise, but should eventually be eliminated as so much surplusage in the struggle for existence, by economy of growth, or even by independent variation when undirected by natural selection. A greater or less time would in different cases be required to effect this reduction, and thus we can understand why they are sometimes allowed to persist into genera, but rarely into families.

Again, if apparently useless specific characters (whether these be new structures or modifications of old ones, slight changes in form, colour, and so forth) are thus regarded as really useless, we should expect that they ought to be of a kind which do not impose much physiological tax upon the organism, since otherwise natural selection would not have allowed them to become so much as specific characters. Well, I have applied this test, and find it is a most general rule that specific characters the utility of which cannot be perceived are such as do not impose any considerable demand for nourishment : either on account of their small size or of their organically inexpensive material, they do not impose much tax upon the organism. Now it is obvious that there can be no connection between utility as disguised and smallness of size or inexpensiveness of material ; while it is no less obvious that there is a close connection between these things and a real inutility.

Lastly, our domesticated varieties occasionally exhibit well-marked and more or less constant characters of a useless kind. Here there can scarcely be any question about the genuineness of the inutility, seeing that the characters have arisen only under domestication, or in the absence of any struggle for existence. Yet these structures are sometimes of the most curious and complex morphology—even more so than innumerable apparently useless structures in the case of natural species.[2]

Argument from Divergence of Character.—Any theory of the origin of species in the way of descent must be prepared with an answer to the question, Why have species *multiplied?* Why have they not simply become transmuted in linear series instead of ramifying into branches? This question Mr. Darwin seeks to answer

[1] Abstract of a Paper read before the Linnean Society on May 6, by George J. Romanes, M.A., LL.D., F.R.S. &c. Continued from p. 340.

[1] For instances of useless instincts see Mr. Darwin's posthumous essay published in my "Mental Evolution in Animals." It is suggestive in the present connection that, just like useless structures, useless instincts, so far as I can find, only occur in species and genera : never in families, orders, or classes.

[2] For a good instance of this see "Variation of Plants and Animals under Domestication," vol. i. pp. 78-79.

"from the simple circumstance that the more diversified the descendants from any one species become in structure, constitution, and habits, by so much will they be better enabled to seize on many and widely diversified places in the economy of nature, and so be enabled to increase in numbers."[1] And he proceeds to illustrate this principle by means of a diagram, showing the hypothetical divergence of character undergone by the descendants of seven species. Thus, he attributes divergence of character exclusively to the influence of natural selection.

Now, this argument appears to me unassailable in all save one particular; but this is a most important particular: the argument wholly ignores the effect of intercrossing with parent forms. Granting to the argument that intercrossing with parent forms is prohibited, and nothing can be more satisfactory. The argument, however, sets out with showing that it is in limited areas, or in areas already overstocked with the specific forms in question, that the advantages to be derived from diversification will be most pronounced. Or, in Mr. Darwin's words, it is where they "jostle each other most closely" that natural selection will set a premium upon any members of the species which may depart from the common type. Now, inasmuch as this jostling or overcrowding of individuals is a needful condition to the agency of natural selection in the way of diversifying character, must we not feel that the general difficulty from intercrossing previously considered is here presented in a special and aggravated form? At all events, I know that, after having duly and impartially considered the matter, to me it does appear that, unless the swamping effects of intercrossing with the parent form on an overcrowded area is in some way prevented to begin with, natural selection could never have any material supplied by which to go on with. Let it be observed that I regard Mr. Darwin's argument as perfectly sound where it treats of the divergence of *species* from one another—*i e.* of the rise of genera, families, &c.; for then physiological barriers are present to prevent intercrossing. But in applying the argument to explain the divergence of *individuals* into *varieties* it seems to me that here, more than anywhere else, he has lost sight of the formidable difficulty in question. For in this particular case so formidable does the difficulty seem to me, that I cannot believe natural selection alone could produce any divergence of character so long as all the individuals on an overcrowded area occupy that area together. Yet if any of them quit that area, and so escape from the unifying influence of free intercrossing, these individuals also escape from the conditions which Mr. Darwin names as those that are needed by natural selection in order to produce divergence. Therefore it appears to me that, under the circumstances supposed, natural selection alone could not produce divergence; the most it could do would be to change the whole specific type in some one direction (the needful variations in that one direction being caused by some general change of food, climate, habit, &c., affecting a number of individuals simultaneously), and thus induce transmutation of species in a linear series—each succeeding member of which might supplant its parent form. But, in order to secure diversity, multiplication, or ramification of species, it appears to me obvious that the primary condition required is that of preventing intercrossing with parent forms at the origin of each branch—whether the prevention be from the first absolute, or only partial. And, after all that has been previously said, it is needless again to show that the principles of physiological selection are at once the only principles which are here likely to be efficient, and the principles which are fully capable of doing all that is required. For species, as they now stand, unquestionably prove the fact of ramification; and it appears to me no less unquestionable that ramification, as often as it has occurred, can only have been permitted to occur by the absence of intercrossing with parent forms. But apart from geographical barriers (which, according to Mr. Darwin's argument, would be inimical to the divergence of character by natural selection), the ramification can only take place as a consequence of physiological selection, or as a consequence of some change in the reproductive system which prevents intercrossing with unchanged (or differently changed) compatriots. But when once this condition is supplied by physiological selection, I have no doubt that divergence of character may then be promoted by natural selection, in the way that is explained by Mr. Darwin.

From which it will be seen that the theory of physiological selection has this advantage over the theory of natural selection in the way of explaining what Mr. Darwin calls diversification of character, or what I have called the ramification of species. This diversification or ramification has reference chiefly to the secondary specific distinctions, which, as we have seen, the theory of natural selection supposes to be the first changes that occur, and, by their occurrence, to induce the primary distinction of sterility. My theory, on the other hand, inverts this order, and supposes the primary distinction to be likewise (in most cases) the primordial distinction. Now, the advantages thus gained are twofold. In the first place, as just shown, we are able to release the principle of natural selection from what appears to me the otherwise hopeless difficulty of effecting diversification of character on an overcrowded area with nothing to prevent free intercrossing. And, in the next place, as we can now see, we are able to find an additional reason for the diversification of character, over and above the one that is relied upon by Mr. Darwin. For, by regarding the primary distinction of sterility as likewise the primordial distinction, we are able to apply to an incipient variety, inhabiting even an overcrowded area, the same principles which are known to lead to diversification by geographical barriers or by migration, as previously explained. In other words, if once we regard the primary distinction of sterility as also the initial distinction, instead of the incidental result of secondary distinctions, Mr. Darwin's argument touching the causes of diversification is not merely saved: it is notably extended by the addition of an independent principle, which, as we know from other evidence, is a principle of high importance in this respect.

Argument from Geographical Distribution.—The body of evidence under this head is too large to be given in an abstract; but the following are some of the chief points.

Mr. Darwin took a great deal of trouble to collect evidence on the two following facts, namely, (1) that "species of the larger genera in each country vary more frequently than the species of smaller genera"; and (2) that "many of the species included within the larger genera resemble varieties in being very closely, but unequally, related to each other." By larger genera he means genera containing many species, and he accounts for these general facts by the principle "that where many species of a genus have been formed, on an average many are still forming." But how forming? If we say by natural selection alone, we should expect to find the multitudinous species differing from one another in respect of features presenting utilitarian significance; yet this is precisely what we do not find. For Mr. Darwin's argument here consists in showing that "in large genera the amount of difference between the species is often exceedingly small, so that in this respect the species of the larger genera resemble varieties more than do the species of the smaller genera." Therefore the argument, while undoubtedly a very forcible one in favour of the fact of *evolution*, appears to me scarcely consistent with the theory of *natural selection*. On the other hand, the argument tells strongly (though unconsciously) in favour

[1] "Origin of Species," p. 87.

of physiological selection. For, the larger a genus, or the greater number of species it contains, the greater must be the opportunity afforded for the occurrence of that particular kind of variation on which the principle of physiological selection depends. All the species of a genus may be regarded as so many varieties which have already been separated from one another physiologically: therefore each of them may now constitute a new starting-point for a further and similar separation—particularly as, in virtue of their previous segregation, many of them are now exposed to different conditions of life. Thus, it seems to me, we can well understand why it is that genera already rich in species tend to grow still richer; while such is not the case in so great a degree with genera that are poor in species. Moreover, we can well understand that, multiplication of species being in the first instance determined by changes in the reproductive system alone, wherever a large number of new species are being turned out, the secondary differences between them should be "often exceedingly small"—a general correlation which, so far as I can see, we are not able to understand on the theory of natural selection.

Another general fact mentioned by Darwin, and now well recognised by all naturalists, is that closely allied species, or species differing from one another in trivial details, usually occupy contiguous areas; or, conversely stated, that contiguity of geographical position is favourable to the appearance of species closely allied to one another. Of course this fact speaks in favour of evolution; but where the question is as to method, I confess that the theory of natural selection appears to me wholly irrelevant. For, in most of the numberless cases to which I allude, the points of minute detail wherein the allied species differ in respect of secondary distinctions, are points which present no utilitarian significance. And, as previously argued, it is impossible to believe that there can be any general or constant correlation between disguised utility and insignificance of secondary distinction.

Now the large body of facts to which I here allude, but which I have not space to detail, appears to me to constitute perhaps the strongest of all my arguments in favour of physiological selection. Take, for instance, a large continental area, and follow across it a chain of species, each link of which differs from those on either side of it by the most minute and trivial distinctions of a secondary kind; but all the links of which differ from one another in respect of their reproductive systems, so that no one member of the series is perfectly fertile with any other member. Can it be supposed that in every case this constant primary distinction has been superinduced by the trivial secondary distinctions, distributed as they are over different parts of all these kindred organisms, and yet nowhere presenting any but the most trifling amount of morphological change? Or, even if we were to suppose this, we have still to meet the question, How were all these trifling changes produced in the face of free intercrossing on the continental area? Certainly not by natural selection, seeing that they are all useless to the species presenting them. Let it then be by changes in the conditions of life, whether of food, of climate, or of anything else. I can conceive of no other alternative. Yet, if we accept this alternative, we are but espousing—in a disguised and roundabout way, to be sure—the theory of physiological selection. For we are thus but hypothetically assigning the causes which have induced the primary distinction in each case, or the causes which have led to the mutual sterility. For my own part, I believe that the assignation would be, in the great majority of such cases, incorrect. That is to say, I do not believe that in the great majority of such cases the trivial secondary distinctions—however these were caused—can have had anything to do with the great primary distinction. What I believe is that all the closely-allied species inhabiting our supposed continent, and differing from one another in so many points of minute detail, are but so many records of one particular kind of variation having taken place in the reproductive systems of their ancestors, and which, so often as it did take place, necessarily gave birth to a new species. The primary distinction thus became the constant distinction, simply because it was in virtue of this distinction—or in virtue of the variation which first originated this distinction—that the species became species; and the secondary distinctions thus became multitudinous, minute, and unmeaning, simply because they were of later origin, the result of spontaneous variability, unchecked by intercrossing with the parent forms, and, on account of their trivial (*i.e.* physiologically harmless) nature, unchecked also by natural selection, economy of growth, or any other principle which might have prevented spontaneous variability of any other kind.

There are many other general facts relating to geographical distribution which lend the strongest countenance to the theory of physiological selection—in particular I may mention the difficulty which Mr. Darwin experiences in accounting for the absence or rarity of transitional varieties between species inhabiting contiguous areas (*loc. cit.*, p. 134), which is just what might have been expected on my theory—but it is time that this abstract should draw to a close.

Relations between the Theories of Natural Selection and Physiological Selection.—The two theories resemble one another in the kind of evidence by which they are each supported. For in neither case is this evidence that of direct observation of the transmutation of species under the influence of the agency supposed: the evidence in each case consists in first proving the facts on which the principle depends, and then showing that the phenomena of organic nature are such as they ought to be if the principle in question has had any large share in their production. But the two theories differ in that while natural selection is a theory of the origin of genera, families, orders, and classes even more than it is of the origin of species; the theory of physiological selection is almost exclusively a theory of the origin of species. Again, the latter theory differs from the former in that the variations on the occurrence of which it depends are variations of a comparatively unuseful, or non-adaptive, kind. Nevertheless, physiological selection must be quite as vigilant as natural selection, and it seizes upon the comparatively unuseful variation of sterility with even more certainty than natural selection can seize upon any useful variation. Lastly, as will have been gathered from the foregoing abstract, the two theories are in no way opposed to one another: they are, in fact, complementary, and the principles with which they have to deal co-operative. For, on the one hand, without the assistance of physiological selection, natural selection would, I believe, be all but overcome by the adverse influences of free intercrossing—influences all the more potent under the very conditions which are required for the multiplication of species by divergence of character. On the other hand, without natural selection, physiological selection would be powerless to create any differences of specific type other than those of mutual sterility and trivial details of structure, form, or colour—differences wholly without meaning from a utilitarian point of view. But in their combination these two principles appear to me able to accomplish what neither can accomplish alone—namely, a full and satisfactory explanation of the origin of species.

Conclusion.—It has not been possible to do justice to the theory of physiological selection within the limits of this abstract. But perhaps enough has been said to show that there is a great deal of evidence in its support; that by regarding mutually sterile species as records of variation in reproductive systems, we are at work, so to speak, on the foundation of the matter; and that we are thus able to explain a number of general facts which do not

admit of being explained by any previous theory. It only remains to add that, if true, the present theory ought to admit of experimental verification. Let well-marked natural varieties of plants growing on the same area be systematically tested with regard to their relative *degrees* of fertility, first within themselves, and next towards one another: let these experiments be made in successive years over a number of natural varieties, by carefully-conducted artificial fertilisation, and by counting the seeds and tabulating the results. In this way experimental evidence would probably be obtained of degrees of sterility between even slight though constant varieties growing on the same areas; and, if so, such evidence would serve as further proof of the present theory. But experiments of this kind, in order to be satisfactory, ought to be conducted by a number of observers in different geographical areas; and my object in publishing so lengthy an abstract of my views in this periodical is that of inducing naturalists in other parts of the world to co-operate with me in carrying out this research. The paper itself, which furnishes fuller particulars as to the way in which such experiments should be carried out, is published in a separate form by the Linnean Society.

THE WOODEND COLLIERY EXPLOSION

QUI s'excuse s'accuse will occur to the minds of many who have followed the details of the disastrous explosion which took place at Woodend or Bedford Colliery on Friday last. We read in the *Times* of the 16th inst.:—"The Four-foot or Crombonke Mine is a very dusty one, and it is considered that at the Woodend pit the dust has increased the extent of the damage." "But to water the mine, as suggested by the Commission, would here be a very difficult operation, because the floor of the mine consists of a species of fire-clay which, as it absorbs the water, causes a lifting of the ground, and so prevents mining operations being conducted." Inasmuch, however, as the floor of perhaps ninety-nine out of every hundred mines consists of the same kind of material, the same argument against watering would hold equally good in most cases, and, if it is allowed to pass, this recommendation of the Commissioners is likely to come to nothing. It has been pointed out more than once in NATURE that the amount of water required to lay the dust is very small—far less than would be necessary to materially affect the floor of a mine in the manner suggested, and it would perhaps be wiser to try the effect in the first place and judge by results rather than to meet the proposition with a simple *non possumus*. We speak thus plainly here, because many of the witnesses who gave evidence before the Commissioners brought forward the very same argument with the same degree of plausibility, and we have reason to believe without having put the matter to a practical test. Many of those who now water regularly, for the express purpose of laying the dust on floors consisting of fire-clay, admit that the water produces no appreciable difference when properly and carefully distributed.

The bursting of the gauze of a safety-lamp, described by one of the survivors, is so contrary to all reason and experience that it cannot be accepted as an explanation of the origin of the explosion. Hundreds, if not thousands, of safety lamps are placed in explosive gas every day when the mines are being tested for the presence of fire-damp, and yet no parallel case has ever been recorded. Under these circumstances we prefer to attribute it to some other still unknown cause. We have yet to learn whether shots were fired in the mine, and if so we have probably not far to look for the explanation.

Up to the present all we know with certainty is that the mine produced very little gas, that it was dry and dusty, and that the explosion was violent but not universal. It would be most interesting, as well as instructive, to ascertain whether any natural local dampness curtailed its extent; but as this is a feature that has not hitherto attracted or received much attention, we are not sanguine that it will be carefully inquired into in the present case. We shall, however, watch the future course of the inquiry, and perhaps again comment upon it for the benefit of our readers.

W. G.

ON THE DIFFERENTIAL EQUATION TO A CURVE OF ANY ORDER

TO Mr. Samuel Roberts (see Reprint of *Educational Times*, vol. x. p. 47) is due the credit of having been the first to show that a direct method of elimination properly conducted leads to the differential equation for a cubic curve: but he has not attempted to obtain the general formula for a curve of any order. By aid of a very simple idea explained in a paper intended to appear in the *Comptes rendus* of the Institute, I find without calculation the general form of this equation. The eft-hand member of it may be conveniently termed the differential *criterion* to the curve. One single matrix will then serve to express the criteria for all curves whose order does not exceed any prescribed number. For instance, suppose we wish to have the criteria for the orders 1, 2, 3, 4:—

Let $m\,\mu$ be used in general to denote the coefficient of

$$h^m \text{ in } \left(\frac{1}{1.2}y''h^2 + \frac{1}{1.2.3}y'''h^3 + \frac{1}{1.2.3.4}y''''h^4 + \ldots\right)^m.$$

Write down the matrix—

$$\begin{array}{cccccccccc}
2\cdot1 & 3\cdot1 & 3\cdot2 & 4\cdot1 & 4\cdot2 & 4\cdot3 & 5\cdot1 & 5\cdot2 & 5\cdot3 & 5\cdot4 \\
3\cdot1 & 4\cdot1 & 4\cdot2 & 5\cdot1 & 5\cdot2 & 5\cdot3 & 6\cdot1 & 6\cdot2 & 6\cdot3 & 6\cdot4 \\
4\cdot1 & 5\cdot1 & 5\cdot2 & 6\cdot1 & 6\cdot2 & 6\cdot3 & 7\cdot1 & 7\cdot2 & 7\cdot3 & 7\cdot4 \\
5\cdot1 & 6\cdot1 & 6\cdot2 & 7\cdot1 & 7\cdot2 & 7\cdot3 & 8\cdot1 & 8\cdot2 & 8\cdot3 & 8\cdot4 \\
6\cdot1 & 7\cdot1 & 7\cdot2 & 8\cdot1 & 8\cdot2 & 8\cdot3 & 9\cdot1 & 9\cdot2 & 9\cdot3 & 9\cdot4 \\
7\cdot1 & 8\cdot1 & 8\cdot2 & 9\cdot1 & 9\cdot2 & 9\cdot3 & 10\cdot1 & 10\cdot2 & 10\cdot3 & 10\cdot4 \\
8\cdot1 & 9\cdot1 & 9\cdot2 & 10\cdot1 & 10\cdot2 & 10\cdot3 & 11\cdot1 & 11\cdot2 & 11\cdot3 & 11\cdot4 \\
9\cdot1 & 10\cdot1 & 10\cdot2 & 11\cdot1 & 11\cdot2 & 11\cdot3 & 12\cdot1 & 12\cdot2 & 12\cdot3 & 12\cdot4 \\
10\cdot1 & 11\cdot1 & 11\cdot2 & 12\cdot1 & 12\cdot2 & 12\cdot3 & 13\cdot1 & 13\cdot2 & 13\cdot3 & 13\cdot4 \\
11\cdot1 & 12\cdot1 & 12\cdot2 & 13\cdot1 & 13\cdot2 & 13\cdot3 & 14\cdot1 & 14\cdot2 & 14\cdot3 & 14\cdot4
\end{array}$$

The determinant of the entire matrix, which is of the tenth order, is the criterion for a quartic curve. The determinant of the minor of the sixth order, comprised within the first six lines and columns is the criterion for a cubic. The determinant of the third order, comprised within the first three lines and columns (subject to a remark about to be made) will furnish the criterion for a conic, and the apex of the matrix is the criterion for the straight line. By adding on five more lines and columns, according to an obvious law, the matrix may be extended so as to give the criterion for a quintic; then six more lines and columns a sextic, and so on as far as may be required.

The remark to be made concerning the determinant of the third order referred to is that it contains the irrelevant factor $2\cdot1$, *i.e.* $\frac{y''}{2}$, so that the criterion for a conic (Monge's) is this determinant divested of such factor. It is *certain* that the next determinant is indecomposable, and is therefore the criterion for a cubic. There is no reason that I know of to suppose that any other determinant except that one which corresponds to the conic, is decomposable into factors. If this is made out, then, observing that the single term which is the criterion for the right line is indecomposable, we have another example of what may be called, in Babbage's words, a miraculous exception to a general law.

A well-known similar case of such miraculous exception I had occasion many years ago to notice in connection with the criteria for determining the number of real and imaginary roots in an algebraical equation. Such criteria may, with one single exception, be expressed

by means of invariants. The case of exception is the biquadratic equation, for which it is impossible to assign an invariantive criterion that shall serve to distinguish between the case of all the roots being real and all imaginary.

It is proper to notice that it follows, from the definition of the symbol $m.\mu$, that its value is zero whenever m is less than 2μ. Thus, in the matrix written out above, the symbols 3·2, 4·3, 5·3, 5·4, 6·4, 7·4 may be replaced by zeros.

The above general result for a curve of any order is actually obtained by a far less expenditure of thought and labour than was employed by Monge, Halphen, and others to obtain it for the trifling case of a conic. I touch a secret spring, and the doors of the cabinet fly wide open.[1] J. J. SYLVESTER

New College, Oxford, August 6

CAPILLARY ATTRACTION[2]

III.

In these other diagrams, however (Figs. 13 to 28), we have certain portions of the curves taken to represent real capillary surfaces shown in section. In Fig. 13 a solid sphere is shown in four different positions in contact with a mercury surface; and again, in Fig. 14 we have a section of the form assumed by mercury resting in a circular V-groove. Figs. 15 to 28 show water-surfaces under different conditions as to capillarity; the scale of the drawings for each set of figures is shown by a line the length of

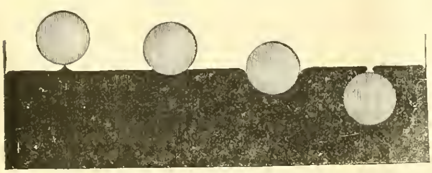

FIG. 13.—Mercury in contact with solid spheres (say of glass).

which represents one centimetre; the dotted horizontal lines indicate the positions of the free water-level. The drawings are sufficiently explicit to require no further reference here save the remark that *water* is represented by the lighter shading, and *solid* by the darker.

We have been thinking of our pieces of rigidified water as becoming suddenly liquified, and conceiving them inclosed within ideal contractile films; I have here an arrangement by which I can exhibit on an enlarged

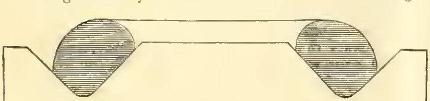

FIG. 14.—Sectional view of circular V-groove containing mercury.

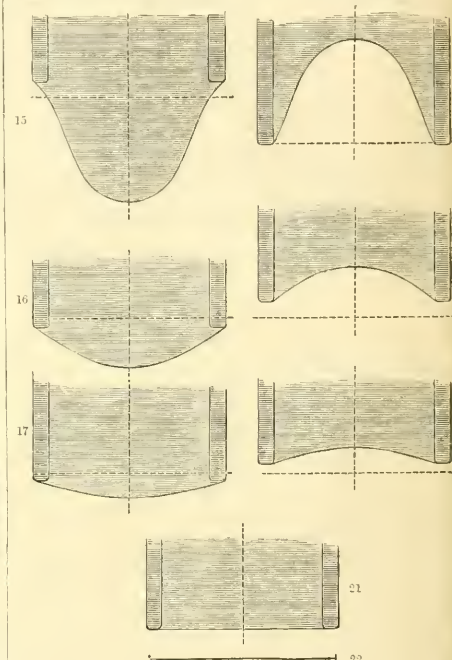
scale a pendant drop, inclosed not in an *ideal* film, but in a *real* film of thin sheet india-rubber. The apparatus which you see here suspended from the roof is a stout metal ring of 60 centimetres diameter, with its aperture closed by a sheet of india-rubber tied to it all round, stretched uniformly in all directions, and as tightly as could be done without special apparatus for stretching it and binding it to the ring when stretched.

I now pour in water, and we find the flexible bottom assuming very much the same shape as the drop which you saw hanging from my finger after it had been dipped into and removed from the vessel of water (see Fig. 16).



FIGS. 15-21.—Water in glass tubes, the internal diameter of which may be found from Fig. 22, which represents a length of one centimetre.

I continue to pour in more water, and the form changes gradually and slowly, preserving meanwhile the general form of a drop such as is shown in Fig. 15, until, when a certain quantity of water has been poured in, a sudden change takes place. The sud-

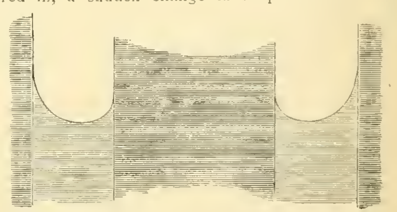


FIG. 23.—Water resting in the space between a solid cylinder and a concentric hollow cylinder.

den change corresponds to the breaking away of a real drop of water from, for example, the mouth of a tea-urn, when the stopcock is so nearly closed that a very slow dropping takes place. The drop in the india-rubber bag, however, does not fall away, because the tension of the india-rubber increases enormously when

[1] Adopting the convention for degree and weight of a differential coefficient usual in the theory of reciprocants the deg : weight of the differential criterion of the nth order will be easily found to be—

$$\frac{n\,.\,\overline{n+1}\,.\,\overline{n+2}}{6} : \frac{\overline{n-1}\,.\,n\,.\,\overline{n+1}\,.\,\overline{n+2}}{8}$$

except that for $n = 2$ it is 3 : 3 instead of 4 : 3.

[2] Lecture delivered at the Royal Institution. Revised and extended by the Author. Continued from p. 294.

the india-rubber is stretched. The tension of the real film at the surface of a drop of water remains constant, however much the surface is stretched, and therefore the drop breaks away instantly when enough of water has been supplied from above to feed the drop to the greatest volume that can hang from the particular size of tube which is used.

I now put this siphon into action, gradually drawing off some of the water, and we find the drop gradually diminishes until a sudden change again occurs and it assumes the form we observed (Fig. 16) when I first poured in the water. I instantly stop the action of the siphon, and we now find that the great drop has two possible forms of stable equilibrium, with an unstable form intermediate between them.

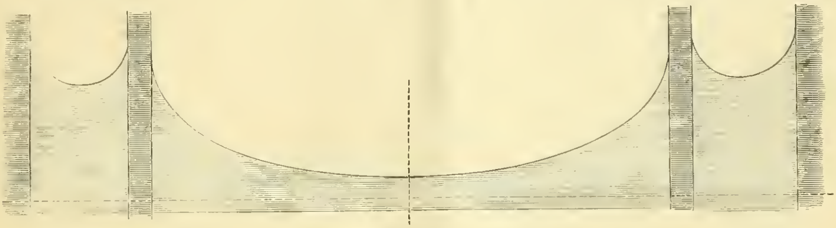

FIG. 24.—Water resting in two co-axial cylinders; scale is represented by Fig. 28.

Here is an experimental proof of this statement. With the drop in its higher stable form I cause it to vibrate so as alternately to decrease and increase the axial length, and you see that when the vibrations are such as to cause the increase of length to reach a certain limit there is a sudden change to the lower stable form, and we may

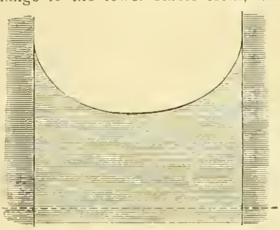

FIG. 25.

now leave the mass performing small vibrations about that lower form. I now increase these small vibrations, and we see that, whenever, in one of the upward (increasing) vibrations, the contraction of axial length reaches the limit already referred to, there is again a sudden change, which I promote by gently lifting with my hands, and the mass assumes the higher stable form, and we have it again performing small vibrations about this form.

The two positions of stable equilibrium, and the one of unstable intermediate between them, is a curious peculiarity of the hydrostatic problem presented by the water supported by india-rubber in the manner of the experiment.

I have here a simple arrangement of apparatus (Figs. 29 and 30) by which, with proper optical aids, such as a cathetometer and a microscope, we can make the necessary measurements on real drops of water or other liquid, for the purpose of determining the values of the capillary constants. For stability the drop hanging from the open tube should be just less than a hemisphere, but for convenience it is shown, as in the enlarged drawing of the nozzle (Fig. 30), exactly hemispherical. By means of the siphon the difference of levels, h, between the free level surface of the water in the vessel to which the nozzle is attached, and the lowest point in the drop hanging from the nozzle, may be varied, and corresponding measurements taken of h and of r, the radius of curvature of the drop at its lowest point. This measurement of the curvature of the drop is easily made with somewhat close accuracy, by known microscopic methods. The surface-tension T of the liquid is calculated from the radius, r, and the observed difference of levels, h, as follows:—

$$\frac{2T}{r} = h;$$

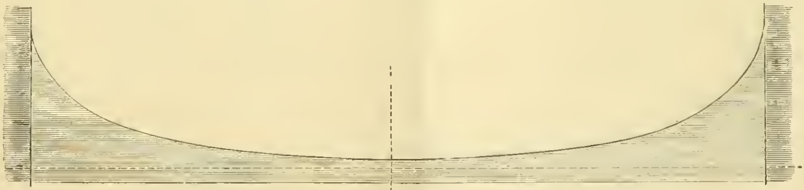

FIG. 26.

FIGS. 25 and 26.—Water resting in hollow cylinders (tubes); scale is represented by Fig. 28.

for example, if the liquid taken be water, with a free-surface tension of 75 milligrammes per centimetre, and $r = \cdot 05$ cm., h is equal to 3 centimetres.

Many experiments may be devised to illustrate the effect of surface-tension when two liquids, of which the surface-tensions are widely different, are brought into contact with each other. Thus we may place on the surface of a thin layer of water, wetting uniformly the surface of a glass plate or tray, a drop of alcohol or ether, and so cause the surface-tension of the liquid layer to become smaller in the region covered by the alcohol or ether. On the other hand, from a surface-layer of alco-

hol largely diluted with water we may arrange to withdraw part of the alcohol at one particular place by promoting its rapid evaporation, and thereby increase the surface-tension of the liquid layer in that region by diminishing the percentage of alcohol which it contains.

In this shallow tray, the bottom of which is of ground glass resting on white paper, so as to make the phenomena to be exhibited more easily visible, there is a thin layer of water coloured deep blue with aniline: now, when I place on the water-surface a small quantity of alcohol from this fine pipette, observe the effect of bringing the alcohol-surface, with a surface-tension of only 25·5 dynes per lineal centimetre, into contact with the water-surface, which has a tension of 75 dynes per lineal centimetre. See how the water pulls back, as it were, all round the alcohol, forming a circular ridge surrounding a hollow, or small crater, which gradually

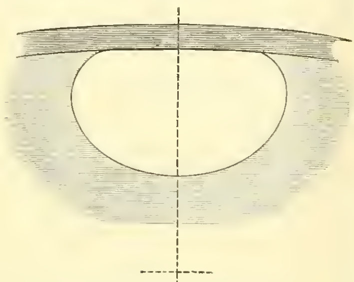

FIG. 27.—Section of the air-bubble in a level tube filled with water, and bent so that its axis is part of a circle of large radius; scale is represented in Fig. 28.

widens and deepens until the glass plate is actually laid bare in the centre, and the liquid is heaped up in a circular ridge around it. Similarly, when I paint with a brush a streak of alcohol across the tray, we find the water drawing back on each side from the portion of the tray touched with the brush. Now, when I incline the glass tray, it is most interesting to observe how the coloured water with its slight admixture of alcohol flows down the incline—first in isolated drops, afterwards joining together into narrow continuous streams.

These and other well-known phenomena, including that interesting one, "tears of strong wine," were described and explained in a paper "On Certain Curious Motions Observable on the Surfaces of Wine and other Alcoholic Liquors," by my brother, Prof. James Thomson, read before Section A of the British Association at the Glasgow meeting of 1855.

FIG. 28.—Represents a length of one centimetre for Figs 24 to 27.

I find that a solution containing about 25 per cent. of alcohol shows the "tears" readily and well, but that they cannot at all be produced if the percentage of alcohol is considerably smaller or considerably greater than 25. In two of those bottles the coloured solution contains respectively 1 per cent. and 90 per cent. of alcohol, and in them you see it is impossible to produce the "tears"; but when I take this third bottle, in which the coloured liquid contains 25 per cent. of alcohol, and operate upon it, you see—there—the "tears" begin to form at once. I first incline and rotate the bottle so as to wet its inner surface with the liquid, and then, leaving it quite still, I remove the stopper, and withdraw by means of this paper tube the mixture of air and alcoholic vapour from the bottle and allow fresh air to take its place. In this way I promote the evaporation of alcohol from all liquid surfaces within the bottle, and where the liquid is in the form of a thin film it very speedily loses a great part of its alcohol. Hence the surface-tension of the thin film of liquid on the interior wall of the bottle comes to have a greater and greater value than the surface-tension of the mass of liquid in the bottom, and where these two liquid surfaces, having different surface-tensions, come together we have the phenomena of "tears." There, as I hasten the evaporation, you see the horizontal ring rising up the side of the

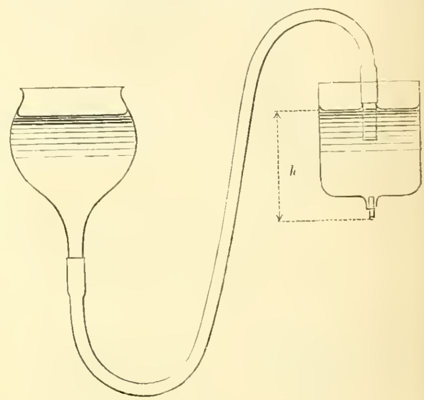

FIG. 29.

bottle, and afterwards collecting into drops which slip down the side and give a fringe-like appearance to the space through which the rising ring has passed.

These phenomena may also be observed by using, instead of alcohol, ether, which has a surface-tension equal to about three-fourths of that of alcohol. In using ether, however, this very curious effect may be seen.[1] I dip the brush into the ether, and hold it near to but not touching the water-surface. Now I see a hollow formed, which becomes more or less deep according as the brush is

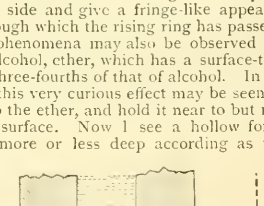

FIG. 30.

nearer to or farther from the normal water surface, and it follows the brush about as I move it so.

Here is an experiment showing the effect of heat on surface-tension. Over a portion of this tin plate there is a thin layer of resin. I lay the tin plate on this hot copper cylinder, and we at once see the fluid resin drawing back from the portion of the tin plate directly over the end of the heated copper cylinder, and leaving a

[1] See Clerk-Maxwell's article (p. 65) on "Capillary Attraction" ("Encyclopædia Britannica," 9th edition).

circular space on the surface of the tin plate almost clear of resin, showing how very much the surface-tension of hot resin is less than that of cold resin.

Note of January 30, 1886.—The equations (8) and (9) on p. 59 of Clerk-Maxwell's article on "Capillary Attraction" in the ninth edition of the "Encyclopædia Britannica" do not contain terms depending on the mutual action between the two liquids, and the concluding expression (10), and the last small print paragraph of the page are wholly vitiated by this omission. The paragraph immediately following equation (10) is as follows:—

"If this quantity is positive, the surface of contact will tend to contract, and the liquids will remain distinct. If, however, it were negative, the displacement of the liquids which tends to enlarge the surface of contact would be aided by the molecular forces, so that the liquids, if not kept separate by gravity, would become thoroughly mixed. No instance, however, of a phenomenon of this kind has been discovered, for those liquids which mix of themselves do so by the process of diffusion, which is a molecular motion, and not by the spontaneous puckering and replication of the boundary surface as would be the case if T were negative."

It seems to me that this view is not correct; but that on the contrary there is this "puckering" as the *very beginning* of diffusion. What I have given in the lecture as reported in the text above seems to me the right view of the case as regards diffusion in relation to interfacial tension.

It may also be remarked that Clerk-Maxwell, in the large print paragraph of p. 59, preceding equation (1), and in his application of the term potential energy to E in the small print, designated by *energy* what is in reality exhaustion of energy or negative energy; and the same inadvertence renders the small print paragraph on p. 60 very obscure. The curious and interesting statement at the top of the second column of p. 63, regarding a drop of carbon disulphide in contact with a drop of water in a capillary tube would constitute a perpetual motion if it were true for a tube not first wetted with water through part of its bore—". . . if a drop of water and a drop of bisulphide of carbon be placed in contact in a horizontal capillary tube, the bisulphide of carbon will chase the water along the tube."

Additional Note of June 5, 1886.—I have carefully tried the experiment referred to in the preceding sentence, and have not found the alleged motion.

WILLIAM THOMSON

OUR FOSSIL PSEUDO-ALGÆ

DURING the last half-century many palæontologists have described anomalous objects, some of which have been regarded as fossil marine Algæ, and others as tracks of various marine invertebrate animals; and since the publication of Darwin's theory of evolution various attempts have been made to utilise some of these in formulating a pedigree for the living types of vegetation. Amongst those who have tried to accomplish this object my distinguished friend the Marquis of Saporta, and his colleague, M. Marion, occupy the most prominent position. They have in several publications described and figured many objects which they believe to have been true marine Algæ, and out of which they have constructed the lower roots of their genealogical tree. But meanwhile there has grown up an enlarging school of palæontologists who look with strong suspicion upon these genealogies; who refuse to recognise the vegetable character of these objects; who believe most of them to be casts of various ridges and furrows, most of which have been tracks produced by creeping invertebrate animals or by the still more mechanical agencies of wind and water. At the head of this school Prof. Nathorst, of Stockholm, stands pre-eminent. An animated controversy sprang up some time ago between M. Nathorst and M. Saporta relative to this subject. Blast and counterblast have succeeded one another, and the latest discharge of palæo-botanical artillery has just been fired off by M. Nathorst in the form of a memoir entitled "Nouvelles Observations sur des Traces d'Animaux et autres Phénomènes d'Origine purement méchanique décrits comme 'Algues Fossiles.'"

Enjoying the privilege of an intimate and valued friendship with both these distinguished palæontologists, I am anxious to do full justice to both. But I must admit that my judgment and experiences bring me into closer agreement with the northern naturalist than with his French antagonist. The interesting subject discussed by them has long occupied my attention, and my conclusions respecting it have not been hastily arrived at.

The question in debate is not whether or not marine Algæ existed in Palæozoic and later geological epochs: on this point Nathorst and Saporta are agreed. The abundance of phytophagous marine mollusks found even in the Cambrian, as in most of the other fossiliferous strata, clearly demonstrates that there must have been submarine pastures upon which they could feed. The question is, are numerous objects, found in strata of marine origin, and believed by some to be fossilised marine Algæ, really such? To this query Saporta answers *Yes*; Nathorst's reply is an emphatic *No*. Hence the elaborate controversial literature of which these two *savants* are the authors. To condense their several articles into an abstract is not easy, but such an abstract of M. Nathorst's latest publication may be attempted, illustrating the general features of the discussion.

Throughout his memoir M. Nathorst rests prominently upon two general propositions which appear to me to be unanswerable. The first is that all or nearly all these debatable pseudo-Algæ stand out in bold demi-relief from the *inferior* surfaces of the rocky slabs to which they are attached, and that beyond their sculptured surfaces they as constantly consist of a mere extension of the rock of which they form a part. Hence Nathorst insists that they are merely convex casts of what were primarily concave grooves or channels on the surface of the subjacent stratum.

In reply to this opinion M. Saporta publishes figures of casts of vegetable fragments in demi-relief, the positions of which on the inferior surfaces of slabs are identical with those of the pseudo-Algæ under discussion. One of these is a fragment of what appears to be a twig of a Conifer, of which the lower side alone is preserved in demi-relief. Nathorst freely admits the possible existence of such specimens, but he regrets Saporta's explanation of them. *Imprimis*, he affirms with inexorable logic, that such examples are so rare and exceptional that they only prove the opposite of the rule which they are alleged by Saporta to sustain. Whenever fragments like these are found embedded in the rocks, they almost invariably display traces of both their upper and lower surfaces; whereas this is scarcely ever the case with the disputed Fucoids, and in the very few instances where such are supposed to have been met with, their entirely exceptional character suggests a very different explanation of them from that proposed by M. Saporta.

It is difficult to understand how a cylindrical object sufficiently dense to produce a deep concave impression upon hardening mud could do so without leaving some trace of its upper surface upon the opposite surface of the sand by which that mud became overlain. Saporta's theory explaining why it does not do so is surely untenable. That theory supposes that an organism half embedded in mud and overlain by sand began to decay at its *upper* surface, which decay ultimately reached the lower surface which rested on the mud; that, as the decay proceeded downwards, the superimposed sand would finally reach the concave mould in the mud which it would fill, and

of which it would permanently preserve the form. Nathorst replies that the decay would follow no such downward course; that it would commence in the softest tissues, wherever they were; and that in such objects as Bilobites and Cruziana, which Saporta believed to be cellular and fistular objects, whilst their outer surfaces were sufficiently hard and resisting to impress their sculpturings upon the underlying mud, the decay would commence in their interior, with the result, in each instance, not of destroying all traces of the upper surface whilst the lower one was preserved, but that both surfaces of the flattened organism would be preserved, as is the case with the Carboniferous Sigillaria and Lepidodendra. Once thus flattened, the organism would no longer be capable of producing the deeply concave groove in the clay to which the specimens in bold demi-relief have been due.

This part of the controversy furnishes Nathorst with another argument. However much compressed, embedded fragments of vegetable matter almost invariably retain some traces of their primitive carbonaceous constituents, however thin the film thus preserved may be. As in the case of many of the Monte Bolca Fucoids, this may be no more than a faint brownish stain on the surface of the stone; whereas such stains, suggestive of the former permanent presence of organic matter, are almost invariably, if not wholly, absent from the pseudo-Fucoids.

In his new memoir M. Nathorst then proceeds to examine in detail the claims of several well-known genera to rank as members of the vegetable kingdom. I must refer such as are interested in the details of this controversy to the original memoir of the Swedish palæontologist. I would only observe that, whilst M. Nathorst denies the accuracy of some of M. Saporta's statements as to the facts in certain instances, in others on which the two palæontologists are agreed he shows that the acknowledged facts are capable of such explanations as lead to conclusions diametrically opposed to those arrived at by M. Saporta.

One of the most important features of M. Nathorst's new memoir is seen in his illustrations. He has invented some simple instruments, by rolling which over some plastic materials he produces impressions, casts of which recall most strikingly the objects known by the generic titles of Cruziana and Harlania.

Whatever ultimate decisions may be arrived at respecting these debated objects, I am compelled to arrive at a conclusion which I have already announced on more than one previous occasion. When it is possible for two observers so experienced as are M. Nathorst and M. Saporta to study the same objects and to arrive at such opposite determinations as to their organic or inorganic character, we must at least conclude that objects capable of receiving such contradictory explanations can have no value when we are considering the evolution of the vegetable kingdom. The evidences of the witnesses in such a controversy must be clear in their testimony and indisputable as to their antecedents.

Manchester, August 11 W. C. WILLIAMSON

NOTES

A TELEGRAM from Grenada, August 16, states that the British observing party for the eclipse of the sun on the 29th inst. has arrived there, and has divided into two. Messrs. Lockyer, Turner, Perry, and Maunder are going to Green Island and Grenville Bay, on the east side of Grenada, and to Carriacou, a small island to the north. Messrs. Darwin, Thorpe, Schuster, and Lawrence will take up their station at Prickly Point, Hog Island.

THE seventeenth meeting of the German Anthropological Society was formally opened on the 11th inst. at Stettin. The gathering is described as a very representative and distinguished one.

THE Yorkshire Naturalists' Union fungus foray will take place on Thursday, September 30. On the following day there will be an exhibition of the specimens in the Leeds Museum, kindly lent for the purpose; and in the evening the usual dinner. Several distinguished mycologists have promised to be present, and no effort is being spared on the part of the officials to make it a success.

LORD DUFFERIN is, it is stated, about to address a memorandum to the Provincial Governments of India regarding technical education, pointing out where the present system fails, suggesting remedies, advising the adoption of a more practical system, and inviting opinions from the Provincial Governments on the whole subject.

WE have received the Smithsonian reports on the progress of physics and mineralogy for the past year. The former is by Prof. Barker, the latter by Prof. E. S. Dana. Physics is treated under the heads general, mechanics (with the subtitles solids, liquids, gases), acoustics, heat (sub-titles production of heat, expansion and change of state, conduction and radiation, specific heat), light (production and velocity, reflection and refraction, dispersion and colour, interference and polarisation), electricity (magnetism, electric generators, electrical units and measurements, electric spark and electric light), obituary, and bibliography. Mineralogy, similarly, is treated under the heads general, crystallography and physical mineralogy, chemical mineralogy, new mineral localities, new minerals, papers on mineral species, bibliography, and obituary.

THE Smithsonian Report for the past year contains a most interesting paper on the "Volcanic Eruptions and Earthquakes in Iceland within Historic Times," translated and condensed from the work of Th. Thoroddsen, by Mr. George Boehmer. The original work appears to be one of enormous research and thoroughness. Mr. Boehmer divides his subject into early accounts, position of the active volcanoes, of which there are eight groups, with a sketch of each, chronological list of volcanic eruptions and earthquakes in Iceland, and finally an extensive bibliography of the volcanoes, earthquakes, and geysers of Iceland.

THREE severe shocks of earthquake occurred at Malta, the first at 8.30 p.m. on August 14, the second at 3.45 a.m. on August 15, and the third at noonday. Three fresh shocks were felt on the evening of the 17th, the first at 5.45, the second at 6.20, and the third at 7.45. They were not so violent as those experienced on Saturday and Sunday, and no damage is reported.

MR. H. B. GUPPY is completing his work on the Solomon Islands and their natives, which will shortly be ready for the press. The work will refer chiefly to the anthropology and geology of this region. It will also treat of the botany, natural history, meteorology, and general resources of these islands, and there will be appended an account of the original discovery of the group as related in the British Museum manuscript of Gallego's "Journal." The chief value of Mr. Guppy's observations will lie in the circumstance that his collections have been examined by the leading authorities on the subjects to which they relate. He hopes to illustrate the work from his own photographs.

WITH reference to Mr. Verbeek's investigations into the Krakatão eruption, which were noticed in NATURE, vol. xxxiii. p. 560, we have received a letter from Herr Retgers, Mining Engineer in Samarang, stating (as indeed Mr. Verbeek had already stated in his work) that the whole of the mineralogical investigations into the composition of the volcanic ashes then thrown out were carried out by him.

The Committee of the Liverpool Naturalists' Field Club begin their report for the past year by observing that for twenty-five years past statistics have been exhausted and lectures also, so far as their usefulness is concerned. "Your Committee, therefore, on this occasion, will spare you figures and forbear admonition, contenting themselves with a bare record of the year's proceedings, and leaving members to draw their own conclusions as to what has been and what might have been done." With such a lugubrious commencement, one might expect that the affairs of the Club were in a "parlous" state, but this is far from being the case. One complaint is that the attendance at the excursions was not satisfactory, and therefore either the number will have to be cut down, or the distances travelled be less. The average attendance was about 60,—which many similar societies would consider an uncommonly good one, especially when it is remembered that some of the journeys were rather long. The Treasurer has the handsome balance of nearly 90*l.* in his hands; the President, the Rev. H. Higgins, delivered an excellent address on "Calcareous Sea-Weeds: an Essay in Comparative Phytology;" the lists of interesting plants noticed on some of the excursions show that the members who did go kept their eyes open; the competition for the prizes appears to have been pretty keen; and there is a tolerably long list of members,—so that, on the whole, notwithstanding the low spirits of the Committee, the case of the Society is far from hopeless. But we trust the members will attend in larger numbers when the Society next goes to the Cefn Caves, Caergwrle, or Humphry Head, notwithstanding the long distances. They will thereby not only add to their own enjoyment and instruction, but will bring relief to the minds of their depressed and anxious Committee.

The greatest balloon in the world has been lately constructed at San Francisco by a Mr. van Tassel. It will hold 150,000 cubic feet of gas, and has been made for the purpose of traversing the American Continent from ocean to ocean. From the bottom of the car to the top of the inflated balloon will be 119 feet, and when filled the diameter will be 68 feet. The car is 21 feet in circumference and has sides 34 inches high; 15 persons can be seated in it.

For several years attempts have been made in Sweden to extract tannic matter from the Swedish species of pine, similar in quality, &c., to that of the American hemlock (*Pinus canadensis*), but without satisfactory results, chiefly on account of the manner in which this is done not being known. Now, however, the question has been solved by a chemist, Dr. Laudin, who, having visited North America for this purpose, has, on his return to Sweden, succeeded in producing tannic matter by a chemical process, which has been found equal to the American, though the colour of the Swedish leather produced therewith is more yellow in colour than the American. It is hoped that this discovery will have the effect of causing a great tanning industry to spring up in Sweden.

The additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*), from West Africa, presented by Mr. C. Palgrave, F.Z.S.; an Alpine Marmot (*Arctomys marmotta*), two Tawny Owls (*Syrnium aluco*), European, presented by Mr. Lionel H. Hanbury, F.Z.S.; a Bank Vole (*Arvicola pratensis*), British, presented by Mr. G. T. Rope; two Derbian Screamers (*Chauna derbiana*) from the North Coast of Columbia, presented by Capt. H. Rigaud; a Peregrine Falcon (*Falco peregrinus*), European, presented by Mr. J. Howard; a Golden-crowned Conure (*Conurus aureus*) from South-East Brazil, deposited; three Long-fronted Gerbilles (*Gerbillus longifrons*), eight Elliot's Pheasants (*Phasianus ellioti*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *AUGUST* 22-28

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 22

Sun rises, 4h. 58m.; souths, 12h. 2m. 42·2s.; sets, 19h. 7m.; decl. on meridian, 11° 44′ N.: Sidereal Time at Sunset, 17h. 11m.

Moon (at Last Quarter) rises, 22h. 6m.*; souths, 5h. 21m.; sets, 12h. 46m.; decl. on meridian, 13° 18′ N.

GEOGRAPHICAL NOTES

We have before us Nos. 5, 6, 7, and 8 of *Petermann's Mittheilungen* for the present year, and Supplement No. 82. The last is a detailed account, by the late Herr Robert Schlagintweit, of the Pacific railways of North America. No. 5 contains a paper on the Xingu Expedition (concluded in No. 6), by Herr Claus, detailing the cartographical surveys and the physical and astronomical measurements made in the course of the explorations. The paper may be regarded as a supplement to the work of Dr. von den Steinen, "Durch Zentralbrasilien," lately published by Brockhaus. Dr. Oppel, in the same number, contributes a statistical paper showing the steady and enormous increase in the population of Europe. No. 7 contains two very interesting and original geographical papers—one by Herr Engelhard on the Island of Saleijer, a Dutch settlement in the Malay Archipelago, situated immediately south of Celebes. The island is described in an exhaustive way, its climate, people, situation, &c., being discussed in some detail. In the second

Dr. Posewitz refers to recent formations in the Island of Banka, off the east coast of Sumatra. This is an instance of an island, undisturbed by volcanic activity, in which erosion and denudation are constantly at work forming the coast. Herr Strass has a paper in the same number dealing with the statistics of emigration from Germany between 1871 and 1884. No. 8, which is the last published, contains a report by Herr Pohle on the expedition sent in 1884 to that part of the coast of South-Western Africa between the Orange River and Walfisch Bay, which came at that time into the possession of Herr Lüderitz. The expedition was intended mainly to ascertain what useful minerals existed in the new territory, and also to study its fauna, flora, and soil. The report is one of considerable length, and deals with all these points. The paper on the forests of North America is based on Prof. Sargent's report, contained in the ninth volume of the United States Census Report for 1884.

THE *Proceedings* of the Royal Geographical Society for August contain several papers of interest. In "Recent Portuguese Explorations in the Zambezi Region" two journeys are described—one between the Zambezi and Pungué, the other between Tete on the Zambezi and Makanga. Mr. J. W. Wells, in a short paper, contributes some information on the delta of the Tocantins, in Brazil, and there is also a summary (the first, we believe, that has appeared in English) of the Von den Steinen exploration of the Xingu. The results of this expedition confirm the conclusion with regard to the geology of the interior of Brazil arrived at by the late Prof. Hartt, and by Mr. Wells, that south of the Amazon valley the whole interior of Brazil was at one time an immense plateau, and that the changes which it has undergone are due to water denudation. But the most important communication in this month's *Proceedings* is the report of the measures adopted by the Council of the Society for the improvement of geographical education. These are of two classes, to be carried out with the co-operation or assistance of the two Universities and the Education Office respectively. Under the first head the Council offer to appoint and pay a lecturer or reader in geography to deliver courses of lectures at both Universities, arranged so as to suit students in the Honour Schools; or, in the alternative, to join with both Universities in appointing and paying a reader in geography. In addition, the Council offers to contribute the funds for an exhibition. In connection with the Education Office, the Council offers various prizes in money and books to pupil teachers. Further, a donation of 30*l.* for the present year is made in aid of the geographical lectures in the University extension courses; copies of the *Proceedings* are to be sent to various public school libraries, and travellers and geographers are to be put in communication with the head masters of public schools. The proposal for a readership in geography at the Universities is obviously the most important of these, and the result of the communications now passing between the President and the Vice-Chancellors will be awaited with much interest.

THE last number (Bd. xxix. No. 4) of the *Mittheilungen* of the Geographical Society of Vienna has for its first article a discussion, by Prof. Penck, of the proportion of the areas of land and water on the surface of the globe. The writer gives at the outset an interesting sketch of the history of the subject, and of the various theories which have prevailed from time to time on the subject, beginning with Columbus, who thought the proportion of land to water was as 6 to 1. Starting from the generally accepted proportion of Wagner as that of 1 to 2·76, Prof. Penck advances various reasons for believing this to be unreliable, especially our ignorance of the regions around the North and South Poles. The blanks on our maps are still too numerous and important to permit of any reasonable approach to accuracy being made. Dr. Paulitschke writes on the hydrography of the Upper Webi, one of the two hydrographic problems of the Somâli peninsula, the other being the Juba, which Capt. Cecchi calls *complicata e misteriosa*. The writer appears to throw much light on the first from his own explorations. He thinks we must seek the source of the Webi in one of the lakes of Gurage. Prof. Blumentritt criticises that part of Dr. Montano's recent work on the Philippines which deals with the ethnology of Mindanao. Accepting for his present purpose (though he refuses to do so as a general proposition) Montano's division of the inhabitants into three main heads—Negritos, Indonesians, and Malays—he advances various reasons for holding that that writer does not arrange the tribes of Mindanao accurately under these heads. These are based chiefly on the languages; but if it does nothing else, the paper demonstrates the wide knowledge which Prof. Blumentritt possesses of these regions. Indeed, for years past he has made every department of research connected with the Philippines his own, until now he is without a living rival.

A REPORT has been received at the Hydrographic Department of the Admiralty from Commander Moore, of the surveying-vessel *Rambler*, relative to the existence of an island lying between L'Echiquier group and Durour Island, recently discovered by Mr. Allison, commanding the British steamer *Fei Lung*, when on the passage from Sydney to Shanghai. This island is covered with trees, and appeared to be 2 or 3 miles long in a north-west and south-east direction, and 100 to 150 feet in height. Both Durour Island and this were visible at the same time from the *Fei Lung* when passing between them. The approximate position as reported is lat. 1° 25′ S., long. 143° 26′ E. The Hydrographer to the Admiralty says that, unless the positions of the islands already on the chart are more inaccurate than they are believed to be, there is little doubt that the island now reported is a new discovery.

THE August number of the *Scottish Geographical Magazine* contains a translation of Col. Fontana's lecture on the Patagonian Andes to the Argentine Geographical Institute, describing his recent journey from Chubut to the slopes of the Andes. The latter are mentioned with great enthusiasm: they teem with fertility, and Nature is as exuberant there as farther north in the Gran Chaco. Finally, the sub-Andean portions of Patagonia are described as the country of the future, being another added to the long list of countries of the future.

IN tome x. fascicule 5, of the *Bulletin* of the Geographical Society of Antwerp, M. van den Gheyn discusses the question whether there is unity, duality, or plurality of races in Australia, and comes to a conclusion in favour of unity. He thinks that the differences found amongst them are to be explained by mixture with the Indonesians on the one side and the Polynesians on the other.

THE French Minister of Public Instruction has intrusted M. Alfred Marche with a mission to the Marianne Islands to study the geography, natural history, anthropology, and ethnography of the Archipelago.

THE AUGUST PERSEIDS

THE shower of Perseids has been a fairly conspicuous one this year notwithstanding the somewhat unfavourable circumstances attending the display. On the nights of August 9, 10, and 11 the nearly-full moon was visible during the greater part of the time available for observation, and robbed the phenomenon of its chief prominence during the evening hours. Those, however, who continued to watch the heavens until after the moon set on the early morning of the 11th must have been rewarded by a tolerably rich exhibition of meteors. The number observable by one person fell little short of 100 per hour, and this rate compared with similar observations in past years proves the late display to have fully maintained its decided character. Numerically this shower of Perseids cannot be placed in the same category as the brilliant meteoric storms of November 13, 1866, and November 27, 1872 and 1885, but it must be remembered that the August shower is one which returns *annually*, and apparently without much variation in its leading features. Its frequent and regular appearances compensate for whatever it lacks in other respects, and it yields many fine meteors of the same type as the Leonids, flashing out with remarkable swiftness, and projecting lines of phosphorescence upon the background of the sky.

The importance of watching every recurrence of the leading meteor showers is acknowledged on all hands, for if we would successfully trace out the modern history and developments of these wonderful systems we must first carefully secure the materials to form the basis of such investigations.

With reference to the shower of Perseids this year, the observations were much interrupted by cloudy weather. Preparation had been made here to commence a look-out during the last week in July for *avant-couriers* of the stream, but the nights were persistently overcast, and it was not until August 2 that a good view was obtained. Clouds were, it is true, somewhat prevalent before midnight, but afterwards the firmament became very clear, and it remained uniformly serene until daybreak.

Watching the eastern sky between 10h. and $14\frac{1}{2}$h., I counted 50 meteors, and of these 12 were Perseids displaying the normal features. The radiant-point was, at $33^\circ + 55^\circ$, not very sharply defined. Some of the best observed paths were slightly discordant, and gave the impression that the focus of divergence was diffused over an area of 3° or 4° diameter.

The following night was cloudy, but August 4 came in very clear, and 58 meteors were seen between 10h. and $14\frac{3}{4}$h. Amongst these were 12 Perseids, and the radiant-point, more contracted and definite than on the 2nd, was now at $37^\circ + 57^\circ$, having increased 4° in R.A. in the interim of 48 hours. The shower exhibited no increase in numbers between the 2nd and 4th; indeed, there appeared to have occurred a slight falling off on the latter date. But on the 4th I saw a duplicate shower of Perseids, the companion radiant being at $48^\circ + 43^\circ$, between α and β Persei, and this position was accurately indicated from seven paths.

A cloudy period supervened between the 4th and 10th, but on the latter night the sky was very clear throughout, though the moon was up until 13h. 30m. Between 10h. and $14\frac{1}{4}$h. I observed 152 meteors, though the watch was not persistent during that interval. The number seen included 122 Perseids with a radiant at $44^\circ + 57\frac{1}{2}^\circ$. At 13h. 6 meteors were noted within 20 seconds, and after the moon had fallen below the horizon the shower developed into one of considerable activity. Between 14h. and 14h. 15m. I counted 22 meteors, so that they were coming at the rate of about 90 per hour for one observer. Some of them were unusually bright. At 13h. 34m. a splendid Perseid appeared in the northern sky, pursuing a path of 13° from $77^\circ + 67^\circ$ to $111^\circ + 67^\circ$. It lit up the whole heavens with a momentary flash, and left a luminous streak, near the end of its path, that remained visible to the eye for nearly 4 minutes. This was by far the most conspicuous meteor seen during the night, and it will probably have been recorded at many other places.

On August 11 the sky was partly clear between $10\frac{3}{4}$h. and $11\frac{1}{4}$h., and 22 meteors were noted, including 15 Perseids from $47^\circ + 57\frac{1}{2}^\circ$. Thus the position of the radiant showed a still further displacement towards the east. The shower had declined greatly since the preceding night, and offered little attraction in the presence of the bright moonlight.

The shifting radiant of the Perseids forms one of the most curious and important details of its display. I first mentioned this feature in NATURE, vol. xvi. p. 362, and have been much interested in reobserving it on many subsequent occasions. Comparing the four positions determined this year, and one obtained on August 13, 1885 (NATURE, vol. xxxii. p. 415), the character of the displacement is well shown, and corroborates the figures given in the *Monthly Notices*, December 1884, pp. 97–8:—

		° °	
1886, August	2	33 + 55	12 meteors
	4	37 + 57	12 ,,
	10	44 + $57\frac{1}{2}$	122 ,,
	11	47 + $57\frac{1}{2}$	15 ,,
	13	51 + 58	6 ,,

On the whole the recent shower may be justly regarded as one fully answering to expectation. It has been quite equal, if indeed it has not surpassed, the Perseid displays as I observed them in 1869, 1871, 1874, 1876, 1877, 1878, and 1880. It is, however, somewhat difficult to institute perfectly fair comparisons. The circumstances affecting two displays are rarely, if ever identical. In some years the shower escapes suitable observation owing to cloudy weather just at the important time. In others moonlight nearly obliterates it. We must also consider that, as the main richness of the stream is limited to a short interval, it will occasionally elude us by occurring in daylight. These varying conditions and hindrances render it unsafe to draw conclusions as to the relative aspect of the annual displays unless the evidence is very complete and satisfactory.

It is well known that an unusually large number of minor systems occur simultaneously with the August Perseids. The positions of many of these are now ascertained with considerable precision. The labours of Heis and Schmidt, ably supplemented by Greg, Alex. Herschel, Zezioli, and others, have furnished a multitude of observations which are satisfactorily accordant as to many of the secondary showers of the epoch. The results obtained in the present year have been extremely productive of tenuous radiants. I select five of these as affording instances of very definite showers:—

No.	1886	Radiant ° °	No. of meteors	Features
1	July 27–Aug. 11	291 + 51	14	Rather slow.
2	July 31–Aug. 11	350 + 51	11	Rather swift.
3	August 2–11	48 + 43	10	Swift, streaks.
4	August 2–4	26 + 42	6	Swift, streaks.
5	July 31–Aug. 2	20 + 58	7	Swift, streaks.

Nos. 1 and 2 I observed also in August 1885 (see NATURE, vol. xxxii. p. 415), when I derived their radiants at $292^\circ + 52^\circ$ and $345^\circ + 53^\circ$ respectively. No. 3, between α and β Persei, I observed in July and August 1877, and again on July 23 25, 1884 (*Monthly Notices*, December 1884, p. 107). No. 4, near γ Andromedæ, has also been pre-observed here in August 1877 and 1879; and No. 5 represents the Cassiopeiads, which have long been known as a pronounced companion shower to the Perseids.

The position No. 2 at $350^\circ + 51^\circ$ lies between Cassiopeia and Lacerta. It was the most prominent of all the minor streams of the August epoch in 1885, and in 1877 I had observed it well both in July and August. It has also been noticed by many others in recent years. Taking an average of fifteen different observations the radiant comes out at $350^\circ{\cdot}2 + 52^\circ{\cdot}1$. This particular shower, by its increasing activity during the past few years, appears to have supplanted Mr. Greg's *Lacertids* at $335^\circ + 52^\circ$, which have evidently not maintained their former strength. It is probable also that during the period of Mr. Greg's researches this August shower at about $350^\circ + 52^\circ$ was comparatively quiescent, for there is no reference to it in his catalogue of 1876. The same may also be said of the system of Cygnids at about $291^\circ + 51^\circ$ (near θ Cygni). Possibly, however, the latter may have been formerly confused with the Draconids (= Greg, No. 78). In the "Annuaire pour l'an 1885, publié par le Bureau des Longitudes" I find that two of the chief showers accompanying the Perseids on August 9–14 are stated as at $345^\circ + 50^\circ$ and $294^\circ + 52^\circ$. My recent observations just described confirm this pair of showers in the most definite manner, and they will doubtless be similarly corroborated wherever systematic observations of the Perseids are conducted.

W. F. DENNING

THE SWISS SOCIETY OF NATURAL SCIENCES

THE annual meeting for this year of the Swiss Society of Natural Sciences opened at Geneva on the 10th instant under the presidentship of Prof. Louis Soret. This precursor of all itinerant scientific societies was founded in 1815 in Geneva, and the present is its seventh meeting in the city of its birth. The members and visitors were received on the evening of the 9th in the *salons* of the celebrated Palais Eynard, which, after being long closed, were opened specially for the occasion. After the presidential address on the 10th, a new committee for the forthcoming period of six years was appointed, with its seat at Berne, the next meeting was fixed to take place at Frauenfeld, in Thurgau, and Prof. Grubenmann was elected president.

Prof. Soret in his address first referred to the advantages offered by Geneva to men who have taken science for their vocation, and then, under the title of "*Des impressions réitérées*," developed a series of new and original ideas on æstheticism analysed by the man of science. The repetition, he said, of the same design, whether in a symmetrical form, or in lined designs, such as we see in tapestry, furniture, or buildings, whether of the same dimensions, or of dimensions regularly decreasing, gives an agreeable impression. It is the same with regular curves, but the æsthetic sensation dwells less in the sensation itself than in the intuition which it gives us of a law. This applies not only to form, but also to sound and to colours. Developing these ideas, M. Soret insisted on the part played constantly by repetitions and similitudes because they evoke by intuition the idea of a law.

M. Marcel Deprez then read a paper on the transmission of force by means of electricity, in which he described his recent experiments between Creil and Paris and the results. M. Rilliet, of Geneva, read the report of a commission appointed to investigate the depth to which light penetrates water. Dr. Heim, of Zurich, read a paper on the deformation of fossils in mountains. He described the modifications which rocks undergo in form even after induration. Under the enormous pressure of the rocks above they may become laminated without any visible solution of continuity in the mass, or any rupture.

The effect on the fossils which they contain is similar; these are sometimes enlarged into the most grotesque forms, and hence Agassiz was misled in distributing the fossil fish of the older rocks into eighty distinct species, a considerable number of which were of the same species but deformed in various ways so as to appear different.

Subsequently the members were present at the inauguration of a monument erected to the memory of Gosse, the founder of the Society. Much interest was attracted by the new geological map of the Republic exhibited in the hall. It has just been completed, and is the fruit of twenty-seven years of the labour of a number of geologists under the superintendence of M. Alphonse Favre, who has now the satisfaction of seeing the end of this great task.

On the second day, in the Botanical Section, Prof. Muller, of Geneva, spoke of his systematic researches into the lichens of the *Graphidæ* group, of which he is about to make a general revision; Dr. Fischer, of Berne, described a new fungus (*Hypocrea*); Dr. Nuesch, of Schaffhausen, read a paper on the origin of Bacteria; and Prof. Schuetzler described a curious moss which grows at a depth of 200 feet in the sub-lacustrine moraine of Yvoire. It contains grains of chlorophyll perfectly formed, and is probably a variety of *Thamnium alopecurum*. Prof. Magnus, of Berlin, recounted his observations on the fecundation amongst aquatic plants, and more especially species of the *Naias*. M. Pittier spoke of the modifications being slowly made in the Vaudois flora, certain plants having disappeared wholly, while new ones have taken their places. M. Casimir de Candolle described his investigations into the action of low temperatures in germination.

In the Section of Zoology and Physiology Prof. Auguste Forel communicated a written memoir of the perception of violet by ants. He came to the conclusion that they perceived it with their eyes, and not through the skin. The so-called photodermatic sense does not appear to exist in ants, or at least is of small importance compared with ocular vision. M. Goll read a paper recording his observations on the fauna of Lower Egypt, especially of the fishes of Fayoum. There exists a well-marked distinction between the fauna of the desert and that of the Nile, particularly in colour. Dr. Zschokke gave some details on the development of the *Scolex polymorphus*, a kind of parasitic worm which he studied at the Naples Zoological Station. He thinks that Wagener's classification of the Scolices is not a natural one. Prof. Blance, of Lausanne, continues his studies of the fauna of the Lake of Geneva, and presented a memoir on a new Protozoa which he discovered in a deep part of the lake, and which he names *Gromia brunneri*.

In the Geological Section Dr. Schmidt, of Freiburg in Brisgau, read a paper on the geological and mineralogical nature of the schists of the Grisons, which, it is now demonstrated, belong to the Jurassic. He spoke particularly of the mica which is one of their constituent elements. MM. de Fellenberg and Baltzer described the remains of great vegetable fossils found at Guttanen in the crystalline schists in the mass of Finsteraarhorn. M. Greppin exhibited a beautiful collection of fossils, not yet determined, of the oolite, found in the Jura in the neighbourhood of Basle. Prof. Renevier, of Lausanne, read a report on the excursions made by the Swiss Geological Society in the Vaudoise higher Alps during the five days preceding the meeting. M. Schardt described the geological structure of the Dent du Midi. M. Steinmann gave an account of a journey extending over two years in the Cordilleras of South America, between Bolivia and Patagonia. He sketched rapidly the characteristics of this great chain. The fossil fauna and flora are almost identical with those of European formations. The Upper Trias, Rhætian, Lias, Jurassic, and Cretaceous are all represented.

Of the pleasures as apart from the business of the meeting it is needless to speak. The Genevese authorities and people gave the members a hearty reception, and the whole town was *en fête*. Among the honorary members elected was Dr. J. H. Gladstone.

THE BRITISH MEDICAL ASSOCIATION AT BRIGHTON

THE annual meeting of the British Medical Association is anticipated not only as an occasion for the association and communion of medical men of all classes, but as an opportunity for, so to speak, taking stock of the progress of medical science and practice during the past year. From the choice of a locality near the metropolis, the meeting this year has been very successful, both as to the numbers attending it and the character of the papers read. From the tone of many of the addresses, indeed, it is easily perceived how intimately chemistry, physiology, biology, and even physics are becoming associated with medicine, and how, as a result of this, the special medical departments of pharmacology and therapeutics, pathology and hygiene, are being modified by scientific methods of investigation.

The subject chosen by the President, Dr. Withers Moore, for his address, viz. the higher education of women, was one which, though of interest to all classes of the community, did not lend much scope for the introduction of new matter. The chief argument on the medical aspect of the question brought forward by Dr. Moore was the statement that the extra tax on woman's intellectual faculties produced by this "higher education" leads to bodily degeneration and to unfitness of the individual for a woman's peculiar social duties. This is admittedly so with those who are subjected to over-pressure; still, the questions as to how far these bad effects are general among the class of women who are subjected to severe intellectual training, and how far these bad effects may be counteracted by judicious hygienic surroundings, remain yet to be solved; and the experiments in the higher education of women now being performed in America and England will no doubt yield results which will practically solve the question.

The address in Medicine, which was given this year by Dr. J. S. Billings, of the United States Army, dealt chiefly with medical politics in America, which, like our own country, needs reform in reference to medical education. It is interesting to note, from the remarks of one so well qualified to judge as Dr. Billings, the great progress made in America in the establishment of laboratories devoted to scientific medical investigation; and it may be confidently expected that by this means important contributions will be added to the stores of medical science.

It is in the departments of pathology and pharmacology that the influence of scientific thought and method is most evident. As Dr. Dreschfeld pointed out in his address before the Section of Pathology, there is in the modern study of pathology a great deal more than was comprised twenty or thirty years ago; for, besides the marvellous advances of morbid anatomy due to the improvement in histological methods and knowledge, the stimulus of experimental physiology has initiated important researches on various morbid processes. Indeed it is difficult to draw a hard-and-fast line between experimental physiology and pathology; for, in many instances, the investigation of physiological function proceeds *pari passu* with that of the loss or inhibition of that function. On the anatomical side pathology is seizing the facts discovered by purely scientific investigators, and applying them with good results. Thus, as Dr. Dreschfeld points out, the application of the researches of Flemming, Heuser, Rabl, and others, on the composition of the nucleus, to the study of the cancer-cell, has shown that this is deficient in chromatin and embryonic in character. Again, the selective action of methylene-blue for certain nervous structures when injected into the living body, as described by Ehrlich, indicates a new method of pathological research by which the condition of these structures under the toxic action of substances may be investigated. If, moreover, as Ehrlich thinks, this selective action is due to the conditions of alkalinity and oxidation in the structure, some light may be thrown by future research on the still very obscure reactions of the nucleus and cell, and, more particularly in pathology, on the chemical changes occurring in the nerves in chronic peripheral paralysis due to poisons, such as alcohol and lead. Though a strong advocate of the study of experimental pathology, Dr. Dreschfeld insisted on the necessity of an investigator having a clear idea of the object and, as far as possible, of the methods of the research which he is undertaking. This point, which is of course the basis of all useful experimentation, is very important in experimental pathology, owing to the peculiar conditions under which experiments on animals are performed in this country.

In pathology, which deals more closely with the facts of disease—disordered structure, disordered function—progress has been rapid, but not more so in its scientific aspect than pharmacology and therapeutics. A great deal of attention has of late years been devoted to this subject, as shown by the rapid accumulation of facts concerning old and new remedies. It is on such an occasion as the meeting of the Association that it is well to

stand still for a moment and see the direction in which modern therapeutics is tending. Connected on the one hand with chemistry and physiology, and on the other with pathology and medicine, it is justifiable to expect that the recent advances in these departments of knowledge would have a stimulating effect on the progress of therapeutics.

Dr. Lauder Brunton, in his address (which we print in full) before the Section of Pharmacology, illustrated one aspect of this influence by discussing the connection between chemical constitution and physiological action. It will readily be seen from a study of his remarks how important an effect the line of research which he indicated will have on the progress of rational therapeutics, which is based on a knowledge of the physiological action of a drug. Dr. Brunton's address shows a hopeful sign of advance in the treatment of disease by scientific methods and not by mere empiricism.

One of the most important communications made to the Association, and deserving of mention here, was that by Prof. O. Liebreich, of Berlin, on lanolin as a therapeutic agent. This substance, which is a cholesterin-fat from sheep's wool, is much more rapidly absorbed by the skin than glycerol-fats or vaselin, this property being probably connected with the fact that in nature it is closely associated with, if not formed by, keratin-containing cells, such as those of the skin, hair, feathers, &c. Such a readily absorbable fat, which is unirritating, and will serve as a vehicle for medicaments, has long been a desideratum, and it is probable that lanolin will be a most important agent in the treatment of skin diseases and of local disorders beneath the skin, as in the joints.

Space does not admit of a discussion of the numerous other interesting subjects, chiefly technical, introduced at the meeting of the Association. The interesting questions brought forward by Dr. Taafe in his address on public medicine included the spread of scarlatina by means of milk, a subject the investigation of which has been undertaken by the Local Government Board, and will no doubt yield important results to preventive medicine.

ON THE CONNECTION BETWEEN CHEMICAL CONSTITUTION AND PHYSIOLOGICAL ACTION[1]

THE meeting of the British Medical Association is not for mutual instruction only; it is also for recreation; and, probably, many members of this Association will utilise the opportunity which a meeting at the sea-side, like the present one at Brighton, affords them of indulging in that excellent occupation for an idle man—of watching the waves on the seashore and speculating how far each of them will come. If one have only half an hour to spare, it is difficult to say whether the tide is ebbing or flowing; it is only by watching for a longer time that one can be certain that the water is really moving in one direction or another. Probably a great part of the charm which this occupation possesses is due to the resemblance which one involuntarily traces between the ebb and flow of waters and that of human affairs—individual, national, or racial. The life of a single man is very short in comparison with the history of race; and it is often very difficult to say whether mankind is advancing or retrograding, unless we compare his condition at epochs widely removed from one another.

On doing this, we find a general consensus of opinion, to the effect that civilisation has steadily advanced; and this advancement is usually divided into four stages, characterised by the nature of the tools or weapons employed. In the first, or Palæolithic Age, man employed weapons or tools of flint roughly chipped into shape and unpolished. In the next, or Neolithic Age, the implements consisted of stone, but they were polished. The next age is characterised by the employment of bronze as a material, and the fourth and highest stage by the employment of iron. These stages are not all marked off from one another, for we find them together in the same country or in different countries. Thus, the age in which at present we live is recognised as the Iron Age, on account of the large employment of that metal; but we find that in various countries stone, more or less rudely fashioned, is still used in the manufacture of weapons or tools. For example, when I was in the Colonial Exhibition lately with Mr. Norman Lockyer, he pointed out a kind of threshing implement, such as is now used in Cyprus. It consists of a flat board, in the under side of which are embedded a number of stone celts exactly like those made by prehistoric man, and perhaps used by him for a similar purpose as well as for axes. In the same way that we recognise four stages in the development of the implements used by man in the arts or in warfare, we may, I think, recognise four stages in the development of the implements he has used in the treatment of disease. In the first stage crude drugs were employed, prepared in the roughest manner, such as powdered cinchona or metallic antimony. In the next stage these were converted into more active and more manageable forms, such as extracts or solutions, watery or alcoholic. In the third stage the pure active principles, separated from the crude drugs, were employed, *e.g.* morphine and quinine. In the fourth stage, instead of attempting to extract our medicines from the natural products in which they are contained, we seek to make for ourselves such substances as shall possess the particular action we desire. Now, just as we find stone and iron implements occasionally used together in the same country, so we find that drugs belonging to the different stages mentioned are used at the same time. For example, we may find crude powders, alcoholic extracts, and pure alkaloids all contained in the same pill. Nay more, we may sometimes give to the patient in addition to all these, a medicine made artificially. But, while this condition still exists, we notice that crude drugs are being less and less used, and their place is gradually being taken by pure active principles. We may say, then, that we are passing at present from the Stone Age into the Bronze Age of pharmacology; and may indeed be said to be just entering on the Iron Age. This age may be said to have begun about twenty years ago, when the researches which my predecessor in this office, Dr. Fraser, made with Prof. Crum Brown upon the connection between physiological action and chemical constitution, inaugurated a new era in pharmacology. They found that, by modifying the chemical constitution of strychnine, they could also alter its physiological action, and convert it from a poison which would tetanise the spinal cord into one which would paralyse the motor nerves.

We might perhaps date the beginning of this age from Blake's attempts to show that a connection exists between the form in which various bodies crystallise, and the mode in which they act upon an animal body. Richardson, too, had observed that, amongst various compounds of carbon, certain differences existed in physiological action which might be supposed to correspond to differences in their chemical composition. And at the same time that Crum Brown and Fraser were making their experiments, Schroff in Vienna, and Jolyet and Cahours in France, had independently arrived at somewhat similar conclusions; nevertheless, I think we may fairly say that it was the experiments of Crum Brown and Fraser which fairly started pharmacology in the new direction in which it has since been steadily advancing. It would be impossible for me to enter at all fully into the recent development of this branch of research, but I think it may be both interesting and useful to try to give you a short and popular account of the chief points already made out; and, in doing so, I may perhaps be excused for using, almost to the extent of abusing, similes which are not precisely exact, but which may be useful in giving you a rough idea of a somewhat complicated subject.

We have all heard of the "flesh-pots of Egypt"; but I find that everybody is not acquainted with the "flesh-pots of Shiloh," though "good little Samuel" has probably been frequently held up before us as an example to be followed, and possibly the naughty sons of Eli as an example to be avoided. When these sons of Eli were priests in Shiloh, their custom was, when any man offered a sacrifice, to send their servants with a "flesh-hook" of three teeth, in his hand, which he struck into the pan, or kettle, or cauldron, or pot; and all that the flesh-hooks brought up the priest took for himself.

It is obvious that what the priest's man brought up would depend very greatly on two things, viz. the contents of the pot and the nature of the hook—whether it were large or small, sharp or pointed, single-pronged or many-pronged. It is obvious, too, that a very slight alteration of the points, by the judicious application of a file or whetstone, might considerably influence the savouriness of the priest's dinner. With the small pots that they were likely to have in Shiloh, it would not matter much what the nature of the handle was; but it would matter

[1] An Address delivered at the opening of the Section of Pharmacology and Therapeutics, at the Annual Meeting of the British Medical Association held in Brighton, August 1886. By Thomas Lauder Brunton, M.D., F.R.S., Lecturer on Materia Medica and Therapeutics at St. Bartholomew's Hospital; President of the Section.

very greatly if the priests had to go fishing in the brazen sea of Solomon, for there, with a short handle, they might not be able to reach the tit-bits in the middle, and if the handle were too long, they might go plunging their hooks about the opposite side of the vessel, with the same result as if the handle were too short. Now, in the drugs which we use in medicine, we may find a certain analogy with these flesh-hooks, some part of the drugs being comparable to the hooks, and others to the handle. Perhaps the analogy would be even more correct if we were to regard the hooks as having movable points, which could be taken off and replaced by others of a different form or sharpness. If we take alkaline salts as an example, we may regard the base as the handle, and the halogen as the hook; and by modifying either of these, we may alter the parts of the body affected and the manner in which they are affected. We might, indeed, compare chloride of sodium, in which we have the chlorine attached to sodium, with the low molecular weight of 23, to a hook with so short a shank that it did not reach the big joints lying in the middle of the cauldron; while potassium, with a molecular weight of 40, was just long enough to do this; and rubidium, with a molecular weight of 85, was so long as to go plunging about on the other side. In fact, we find that this is very nearly what occurs in the muscles of the animal body after the administration of the chlorides of sodium, potassium, or rubidium; for, while potassium chloride is a powerful muscular poison, the action of sodium and rubidium chlorides on the muscles is very slight.

We have seen what changes would follow alterations in the shank of our flesh-hook; now let us see the effect of altering the prongs. If we put on a small one like chlorine, it may go dragging about catching everything, but bringing out nothing; a bigger one, like bromine, may lay hold of a lung or a brain; and a bigger one still, like iodine, may lay hold of a big joint. Now, what we find in the body seems to be somewhat similar. The chlorides circulate in the blood without producing any marked alteration beyond that which is due to the substance with which the chlorine is combined. The bromides attack the brain and nerve-centres, and the iodides tend more especially to affect the muscles and the glands.

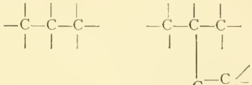
It is evident that another important factor besides the sharpness of the hooks is the number of prongs, and the three-pronged hook seems to be the generally effective one. Now, in pharmacology, there is one substance—nitrogen—which appears sometimes to have three, and sometimes five prongs, or affinities, as chemists term them, and it is a substance having a very general and powerful influence over the body. When combined with hydrogen in the form of ammonia or of ammoniacal salts, it affects nerve-centres, motor nerves, and muscles, tending first to stimulate and then to paralyse them. But, as we would expect, the effect of the ammonia is modified by its combination with iodine, chlorine, and bromine; and we find that, while the ammonium-chloride generally attacks the spinal cord and causes irritation, ammonium-iodide paralyses the motor nerves and muscles.

When nitrogen has oxygen combined with it in place of hydrogen, so as to form nitrous acid, its action is exerted more especially upon the blood and blood-vessels, so that it causes the blood to become chocolate-coloured, and the blood-vessels to dilate. This power of dilating the vessels is sometimes exceedingly useful in the treatment of disease; and we have been enabled to vary the action of our drugs so as to attain, to a great extent, the end we desire, by our knowledge that the action depends upon the nitrous acid, and not on the substance to which the acid may be attached; or, to return to our own comparison, the effect depends on the nature of the hook rather than on the kind of shank to which it is attached. Thus, where rapid dilation is desired, we use nitrite of amyl; but where a slower and more prolonged action is desirable, we employ nitrite of soda or nitro-glycerine.

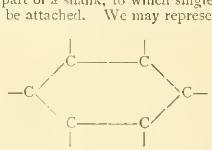
In some useful tools we have the two ends serving different purposes: one end, for example, being a hammer and the other end a claw for extracting nails; and we can easily imagine a flesh-hook constructed on the same principle, one end, let us say, having the prongs widely apart, and the other the prongs close together. With such a hook, it is evident that the viands which were fished up would be different according as one or other end was put into the pot, for the close prongs would bring up delicate little pieces which would simply slip through the wide ones. If we carry our illustration a step further, and suppose this hook to consist of two parts attached to one another by certain prongs, while others were left free, we can see that, if only one prong were left free in each part, but these prongs were of different shapes, the pieces obtained by the man using it would be of a different kind, according as the prong belonged to one end or the other. Now we seem to find something of this sort in the union of nitrogen with carbon. Carbon is a substance with four affinities, while nitrogen appears sometimes to have three and sometimes to have five. When the nitrogen and the carbon are united in such a way that four affinities of each are connected together, leaving one free affinity or prong belonging to pentad nitrogen, thus, $-N \equiv C$, the compound is exceedingly poisonous; whereas, when the free affinity or prong belongs to the carbon and the other three affinities are joined to triad nitrogen, thus, $-C \equiv N$, the compound is comparatively innocuous.

This fact shows us how very important the nature of the free affinity in the compound is in regard to physiological action.

We have just pictured to ourselves an instrument of two parts, joined together by small hooks, and consisting, in fact, of two links. In this instrument the links differ a good deal from each other; but one link—namely, carbon—has a great power of uniting with itself, so as to form long chains, straight or branching, thus—



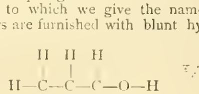
It also forms what we may possibly regard as close chains, so stiff as to act the part of a shank, to which single hooks or long open chains may be attached. We may represent it graphically thus—



Now, if any of Eli's successors wanted to fish in Solomon's brazen sea with hooks attached to a flexible chain instead of to a stiff shank, the results of his fishing would not only depend on the hooks he used, but on the length of the chain, on the kind of chain, single or branching, and on the position of the links to which the hooks were attached.

Now, in the series of chemical substances to which alcohol belongs we have an illustration of the modifications in physiological action which are produced by the length of the chain, the kind of chain, and the position of the hooks. The links, in the case of alcohol, consist of carbon atoms attached to each other by one affinity, so that each terminal atom, or link, has three affinities, or prongs, and the intermediate links have two each unattached, thus—

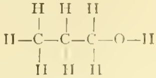
We may regard one prong of one terminal link as furnished with a sharp point, to which we give the name of hydroxyl, while all the others are furnished with blunt hydrogen points, thus—



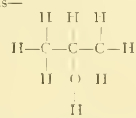
All the alcohols attack the nerve-centres, and paralyse the brain, the spinal cord, and the centres of organic life in the medulla oblongata. In large doses they all produce death, and the longer the chain the more deadly do they become, until the chain is so heavy that it can hardly be used at all, or, in other words, till the alcohol becomes so solid that it will not readily enter the body and produce its toxic action.

If we fix the sharp hydroxyl on one of the intermediate links, instead of the end one, we would naturally expect that it might simply scratch the pieces of meat instead of pulling them out, as it might do if it were attached to the terminal link; and this

is exactly what we find in the case of alcohol. For example, primary propyl alcohol,—

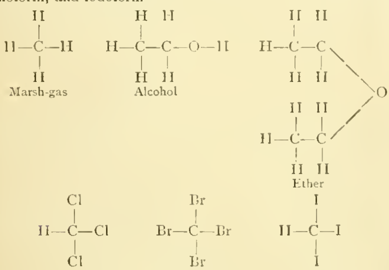


where the hydroxyl is attached to the terminal link, appears to produce steadily increasing paralysis of the nerve-centres; but secondary propyl alcohol, where the hydroxyl is attached to an intermediate link, thus—



scratches up or stimulates the nerve-centres before it paralyses them (Efron Pflüger's *Archiv*, Band xxxvi., 1467).

The whole of the carbon compounds, formed on the principle of an open chain, appear to have an action more or less like that of alcohol, though these are modified by the nature of the substances which "tip," as it were, the free affinities of the carbon links. Thus, marsh-gas, alcohol, ether, chloroform, bromoform, and iodoform—



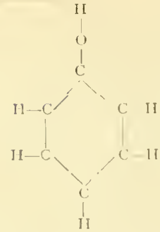
Marsh-gas Alcohol Ether

Chloroform Bromoform Iodoform

all tend to paralyse nerve-centres, and to exert an anæsthetic action; but the chloral in the chloroform tends to make the substance paralyse the heart more quickly than marsh-gas, alcohol, or ether, which contain hydrogen alone, or hydrogen and oxygen; and in iodoform the effect of the carbon is to a great extent swamped by the iodine.

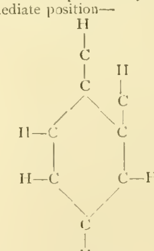
It is to Liebreich's recognition of the fact that similar carbon compounds possess a similar anæsthetic action that we owe the discovery of chloral. The knowledge of the depressing action on the heart of chlorine in such compounds led Schmiedeberg and Cervello to search for a hypnotic substance which should not contain chlorine, with the result that paraldehyde has been added to our therapeutic *armamentarium;* and the stimulant action of ammonia led Schmiedeberg to introduce a new hypnotic, urethane, which, like chloral, will produce sleep, but, instead of weakening, will stimulate the heart, and is thus admissible in cases where chloral might be dangerous.

Let us now turn to the other class of carbon compounds in which the atoms are arranged so as to form a close chain, or, as we may call it, a stiff nucleus or shank, to which either single hooks or open chains may be attached. This group of carbon compounds is termed the aromatic series. The substances belonging to it differ from those of the open chain or fatty groups, inasmuch as they tend to stimulate the nerve-centres, and produce convulsions or spasms before paralysing them. But the most marked property which they possess appears to be their power of reducing temperature, and of destroying low forms of life, so that they act both as antipyretics and as antiseptics. We have seen that in the open chains of the fatty series of carbon compounds, the increased number of links appears to increase the activity of the compound, and a condition which is similar, in some respects at least, is to be found in the aromatic series. For example, in phenol or carbolic acid, as it is usually termed, we have one hydroxyl terminal, just as in ordinary alcohol; the other carbon affinities being saturated with hydrogen—

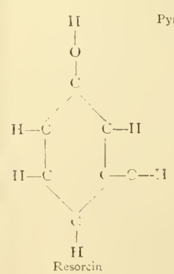


When these hydrogen atoms are replaced by methyl, the antiseptic power of the phenol is increased, and the increase appears to be in proportion to the number of methyl groups which are introduced into the compound. Turning again to our old illustration of the flesh-hooks, we might compare the benzene nucleus to the shank with six points, each of which might be armed either with a sharp hydroxyl hook, or with a blunt hydrogen one, or with a carbon chain. The more the blunt hydrogen hooks were replaced by chains, the more thoroughly would they sweep the pot; and, in fact, we may say that the more chains there are instead of hydrogen, the more thorough is the antiseptic action of the compound.

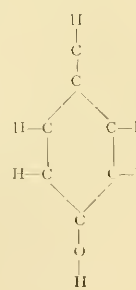
In the case of antiseptics, all that we want is to insure a thorough destruction of the microbes, which give rise to putrefaction or disease; but when we come to deal with antipyretics we have a more complicated problem before us, for we wish to reduce the temperature in man or the higher animals, while at the same time we have to avoid producing any marked action on the nervous system in the way either of spasms or paralysis, and also to avoid depressing the circulation and causing collapse. Now several bodies nearly allied to carbolic acid, and differing from it only in the fact that the benzene nucleus in them has two hydroxyl groups attached to it instead of one, as in carbolic acid, have a strong antiseptic power. These bodies are hydroquinone, resorcin, and pyrocatechin; they all have an antiseptic action, but the strength of their action is very different, resorcin having only one-third of the strength, and pyrocatechin only one-fourth of that of hydroquinone. This difference in strength shows us here, also, how important the position of the hydroxyl groups is; because, in pyrocatechin they are close together, in hydroquinone they are as far apart as they can be, and in resorcin they keep an intermediate position—



Pyrocatechin



Resorcin



Hydroquinone

But these bodies, perhaps from their simple structure, appear to be adapted to attack all parts of the animal organisation, and they are apt to affect the nervous system and circulation. In order to avoid these disadvantages, various attempts have been made to obtain bodies of a similar but more complicated structure, which should have a more specialised action, and would lower the temperature while leaving the nervous system and circulation unaffected. These attempts have been more or less successful, and we owe to them the introduction of three new remedies—kairin, thallin, and antipyrin. The former two, after a brief period of trial, have been found more or less unsatisfactory; but the latter is perhaps, upon the whole, the best antipyretic that we possess, reducing the temperature and, at the same time, having few disadvantages. Salicylate of soda is nearly allied in chemical constitution to resorcin, and as a general antipyretic it is almost equal to antipyrin, and superior to it in cases of rheumatic fever. It is possible that we may still obtain antipyretics more powerful than any we yet possess, and specially adapted to the febrile conditions arising from different causes, for these antipyretics do not appear to be equally successful in different kinds of fever. Antipyrin is best in hectic fever, and salicylate of soda in rheumatic fever, but an antipyretic which will be thoroughly satisfactory in typhoid fever is still a desideratum.

I have said that antipyrin is generally free from any disagreeable action; but this is not always so, for it sometimes may produce collapse. This shows us that in the action of all our drugs we have two factors to consider, namely, the drug itself and the body into which we introduce it. We have just been considering the alterations in physiological action which may be produced by changes in the chemical constitution of our drugs; but there is another factor which is perhaps more difficult to investigate, and still more important in the treatment of disease, namely, the condition of our patients. The failure of our drugs to produce the effects we desire is one of the most trying occurrences in medical practice. Thus, in fever, we sometimes find that drugs will not reduce the pulse as they do in non-febrile conditions, and digitalis in pneumonia sometimes appears to have lost its sedative action on the heart altogether. Some years ago I thought that possibly this might be due to the high temperature producing paralysis of the nervous apparatus which restrains the heart, and supposed that the peripheral ends of the vagus in the heart might be paralysed. I then made some experiments, which showed that I was wrong in this supposition. Several years afterwards my friend Dr. Cash and I made some further experiments, which showed that the failure of digitalis to slow the heart in febrile conditions is really due to paralysis of the regulating nerves of the heart; but the part of them which is paralysed by the heat is their roots in the medulla, and not their endings in the heart.

In other experiments which we made together we found that the muscle of a frog poisoned by barium could be restored to its normal condition by a high temperature, and also by the application of potash salts. It occurred to us that, if we could saturate the body of an animal with potassium, we should be able to render it proof against the poisonous action of barium. On trying this, we succeeded in rendering animals so far resistant to the action of the poison that they were alive and well after animals of similar size, but unprotected, had succumbed to the action of the same dose of poison, although we did not succeed in ultimately saving the animals.

But Dr. Cash has pursued this line of investigation far beyond the limits of our mutual research, and he has obtained results which seem to me to be amongst the most extraordinary and the most promising in pharmacology. Knowing, as he did, that corrosive sublimate was an exceedingly powerful disinfectant, it occurred to him that it might be more harmful to disease-germs than to the bodies of higher animals, and that he might be able, by the introduction of the poison into the body of an animal, to render it insusceptible to zymotic diseases. A similar idea had occurred to Koch, who injected corrosive sublimate into animals after previously inoculating them with anthrax; but his experiments failed, while Cash has proved successful by introducing the corrosive sublimate before inoculating with anthrax, and thus giving the drug the start of the disease. These experiments acquire an additional interest from the fact that M. Pasteur, although uncertain regarding the exact mode in which his process of inoculation for hydrophobia has brought about such satisfactory results, is disposed to think that the agent which prevents the disease is a chemical substance, and not a microbe.

When we look back for twenty years and see how far pharmacology has advanced since Crum Brown and Fraser's experiments directed it into a new path, we may hope that twenty years more may not only have greatly added to our stock of new remedies, but will have enabled us so to ascertain the condition of our patients that, either by the proper modification of a single remedy, by the proper admixture of remedies, or by proper changes in the food or surroundings of each patient, we may insure the action we desire, and we shall not have to feel, as we painfully do at the present, that our patients often die for lack of knowledge, not on our part, but on that of our art.

Nothing is more painful to a medical man than having to answer in the negative the agonised appeal, "Oh, doctor, can you do nothing?" of those who see passing away friends who are dearer to them than their own life. It is because we medical men know the value of human life and the extent of human suffering; because we are called upon to prolong the lives of those whom not only their friends but their country and the world at large can ill spare; because we must, if possible, relieve pain sometimes amounting to extreme torture in the sufferers themselves, and felt hardly less keenly by their friends, that we consider it is not only permissible, but is our imperative duty to gain the knowledge we require to attain our object, even though we sacrifice the lives of animals, and inflict upon them some pain—never wantonly, never carelessly, and almost always slight in comparison with what we often see our patients feel. Moreover, the lower animals suffer from disease as well as men, and we may hope that the advance of pharmacology will give us the means of relieving pain and prolonging life in them as well as in man.

SCIENTIFIC SERIALS

Journal de Physique, June.—P. Garbe, experimental researches on radiation. Examination of the formulæ proposed by Dulong and Petit, by E. Becquerel, by Violle, and by Stefan. The author holds Stefan's law to be true for absolutely black bodies only. The verifications have been made by spectrophotometric measures of glow-lamps fed from accumulators.—G. Wyrouboff, the structure of crystalline bodies endowed with rotatory power. This is a remarkable paper, traversing several conclusions hitherto believed to be proven. The author states that the alleged necessary and constant relation between rotatory power and the existence of facets indicating non-superposable hemihedry is untrue, for of eighteen such substances known, only four have been proved to have such facets, while the nitrates of lead and of baryta which are cubic with facets of this kind have no rotatory power. The author now propounds the view, which he supports by the discovery of striated structures upon the facets in question and by various strong arguments, that the real physical cause of this rotatory power is that such crystals consist of superposed laminæ crossing at different angles, and possessing biaxial refraction. In fact, he holds that these substances are only pseudo-symmetrical, and that the built-up mica plates of Reusch which show rotatory power are actual types of the phenomenon in general. He particularly refers to the optical behaviour of amethyst, and further declares that he has succeeded in proving that the true crystalline form of sulphate of quinine is clinorhombic. He regards as absolutely illusory, in the vast majority of cases, the so-called measurement of the angle of rotation by these substances.—L. Laurent, practical methods for the execution of objectives intended for instruments of precision. This paper describes means for testing during process of manufacture the curvatures, &c., of lenses intended for spectroscopes, goniometers, and such instruments.—Th. and A. Duboscq, saccharimeter for white light. This saccharimeter has a Senarmont polariscope placed between the polariser and analyser. The Senarmont polariscope consists of four wedges of quartz disposed so as to show two fringes with black central band, which in the dark field are situated exactly in line with one another. On introducing any substance that rotates the plane of polarisation, the fringes move right and left. A quartz compensator is added.—J. Voisenat, influence of nature and form of conductors upon the self-induction of an electric current. A summary of the recent papers of Hughes and H. F. Weber.—K. Angstrom, on the diffusion of radiant heat from plane surfaces.—Ch. Soret, researches on the refraction and the dispersion of the crystallised alums.—E. Wartmann, the compensated rheolyser. This instrument consists of a circular modification of Wheatstone's bridge with mercurial conductors.—R. Pictet,

new freezing-machines. Notes on industrial applications of a new liquid, namely a mixture of sulphurous acid and carbonic acid obtained on the commercial scale by the action of sulphuric acid on carbon.—J. Maurer, influence of altitude on diurnal variations of declination.—H. Schneebeli, absolute value of coefficient of friction of air. The results, which agree with Obermeyer, were made by Graham's method.—H. Schneebeli, experimental researches on the impact of elastic bodies.

Bulletins de la Société d'Anthropologie de Paris, tome ix. fasc. 2.—Continuation of M. Topinard's paper on the cephalic index. In his revised system of nomenclature M. Topinard virtually rejects Broca's method in favour of the quintuple division adopted by Prof. Flower, and generally followed by English and American anthropologists. For his old terms of "*sus*" and "*sous*" he further adopts those of "ultra" and "hyper." Thus, for example, while he considers that the true dolichocephalic group is represented by the index of 70–74 inclusive, his ultra- and hyper-dolicho- subdivisions exhibit respectively the indices of 60–64 and 65–69. The medium group standing between the dolicho- and the brachy-cephalic limits he characterises as "mesaticephalic," with an index of 75–79 inclusive; while his brachycephalic divisions range from 80, beginning with the mean representatives of the groups, to 94 as the extreme limit of the ultra-brachycephalic index.—At a later meeting, M. Topinard drew attention to the necessity for using greater exactitude in the definition of the methods to be employed in making anthropometric determinations, those of M. Bertillon as set down in his instructions regarding anthropometric identification being, in his opinion, at once complex and inexact.—On the so-called "Lenape" stone, by M. de Nadaillac, whose opinion of the possible genuineness of the stone is, as he informs us, based only on the testimony of others.—On the occurrence of amber in the prehistoric graves of the Département des Basses Alpes, by M. Bonnemère. These finds were formerly so frequent that the peasants in some districts used amber for lighting their dwellings, and hence it was locally known as "peïra cremarela," or burning stone. This name is still applied to it at Salignac, where many of the villagers are in possession of amber, all of which is more or less red in colour.—At a later meeting, M. Bonnemère described to the Society some curious bronze disks found by M. Ollivier in graves near Salignac, and which appear to have been used to strengthen the outer surface of cuirasses and other forms of protective armour. In a cemetery in Carniola, belonging to the early Iron Age, a helmet has been found composed of similar bronze knobs fastened in rows to an inner skin lining.—Anthropology and philology, by M. Beauregard. The object of the writer is to show the importance of the comparative study of languages to determine the usages, and moral and mental status of various nations. He specially passes in review the languages of Egypt and South Africa, Mexico, Peru, and the Red Indians, indulging in many fanciful deductions regarding assumed ethnic affinities.—On the origin of life, by M. Fauvelle. The author believes that modern science justifies the theory that the simplest forms of green Algæ represent the earliest manifestations of organised beings, in which chlorophyll was the active agent.—On impregnation, and the influence exercised on subsequent offspring by the first conception, by M. Fauvelle.—On the effects of long and short periods of military service in the French army on the health and physical development of the men, by M. Lagneau.—On the origin of the fabrication of glass, by M. Mortillet.—Morphological description of the brain of Gambetta, by MM. Chudzinski and Mathias Duval. This extremely minute report of the *post-mortem* examination, undertaken at the instance of the Society, is illustrated by numerous sectional drawings of the various convolutions, which exhibit a remarkable degree of complexity, and an unusual regularity in the arrangement of the folds.—M. Beauregard laid before the Society various objects obtained from the Gauchos of the Pampas, including the curious "botas de potro," or boots made from the skin of the hind legs of horses, mules, or oxen.—On the exploration of the tumulus of Kergouret at Carnac, in 1885, by M. Gaillard. A few implements and a diorite hatchet are almost the only finds yielded by the recent explorations of these dolmens, which were nearly destroyed, and their contents almost wholly removed at the time of their original discovery about twenty years ago.—Report, by M. Hamy, of the results of the explorations, conducted by M. Charney, in the mountainous region of Popocatapetl, in Mexico. Unusual interest attaches to these researches, which have brought to light the existence of two ancient Mexican cemeteries, in one of which the remains belonged exclusively to young children. Among the numerous fragments of bones were a great mass of broken jars and vases decorated with various emblems of the divinities Chalchiutlicue and Tlaloc, to the latter of whom young children were sacrificed on high places to secure rain.

Bulletin de l'Académie Royale de Belgique, June.—On the origin of the phosphate of lime in the brown chalk phosphatic beds of Ciply, by F. L. Cornet. These beds, which have a mean thickness of 21 metres, and about 18 per cent. of phosphate, are shown to be undoubtedly of animal origin, as attested by the large proportion of nitrous organic substances contained in them. The brown chalk appears to have been deposited in a shallow sea inhabited by a numerous fauna of invertebrates, fishes, and large Saurians. The deposits were slowly formed in tranquil waters during a long geological epoch, as shown by the great thickness of the phosphatic beds, the perfect regularity of the layers, and the state of the fossil shells found in them. These deposits, which occur nowhere else, may have been caused by the periodical destruction of fish, such as at present occurs annually in the Gulf of Aden.—Note on the parallelism between the Carboniferous Limestone of North-West England and Belgium, by L. G. de Koninck. It is pointed out that the synchronism of these various systems is far from being fully established. The Tournai formation would appear to be older than the English fossiliferous mountain limestone, while the Visé rocks may be contemporary of the Yoredale series. On the other hand, the zone of *Productus giganteus* seems to have acquired a far greater development in the north of England than in Belgium.—Remarks on the law regulating the tension of fluids, by P. de Heen. The formula recently announced by the author is here shown to apply not only to stable fluids, but also to those whose physical constitution varies with the temperature.

SOCIETIES AND ACADEMIES

Sydney

Linnean Society of New South Wales, June 30.—Prof. W. J. Stephens, F.G.S., President, in the chair.—The following papers were read:—Note on *Ctenodax wilkinsoni*, by William Macleay, F.L.S. It is here explained that the fish described by Mr. Macleay under the above name has been ascertained by Dr. Ramsay, of the Australian Museum, to be closely allied to *Tetragonurus cuvieri*, of Risso. Some remarks are also made on the habits and affinities of the fish.—Notes on the recent eruptions in the Taupo Zone, New Zealand, by Prof. Stephens, M.A., F.G.S. In this note the author gives particulars of the late volcanic disturbances, and such information as to the geographical and geological features of the district, as may perhaps enable those living at a distance to understand more clearly the accounts of the recent outbreak which have already appeared in the newspapers.—Notes on Australian earthworms, Part I., by J. J. Fletcher, M.A., B.Sc. Up to the present time but three Australian earthworms have been described, *Lumbricus novæ-hollandiæ*, Kinberg, and *Digaster lumbricoides*, Perrier, from N.S.W., and *Megascolides australis*, McCoy, from Victoria. In this paper a fuller account is given of Kinberg's species, and descriptions are given of six new or undescribed worms from the rich volcanic soil of Burrawang and of Mt. Wilson. Of these, two species (*P. coxii* and *P. australis*) are referred to Schmarda's genus *Perichæta;* two others (*N. camdenensis* and *N. grandis*, are included in a new *intraclitellian* genus *Notoscolex;* a fifth (*Didymogaster silvaticus*) also is *intraclitellian*, but differs from *Notoscolex;* and the sixth (*Cryptodrilus*) is *postclitellian*, with eight rows of setæ, but is different from *Digaster*. Three of these, as far as is known at present, occur only at Burrawang, one at Mt. Wilson only, one is common to both localities as well as Sydney, and one occurs at Burrawang, Springwood, and Jervis Bay. Mr. Fletcher has heard of the occurrence of worms, some of them very large, in the Hunter and Manning River districts, and probably these, as well as Illawarra, the Richmond and Clarence districts, and other parts of the colony will yield, when systematically searched, a good harvest of earthworms. He therefore appeals to the members of the Society resident in these or other localities, either for information or for specimens put alive into good methylated spirit, or sent alive packed in a tin box or large bottle, with a little earth and plenty of damp moss. Information as to the existence or otherwise of earthworms in

the plains of the interior would also be very valuable.—Notes on the distribution of *Ceratella fusca*, Gray, from the coast of New South Wales, by John Brazier, C.M.Z.S. A number of instances are given of the occurrence of this Hydrozoon near the Heads of Port Jackson. Mr. Brazier also mentions that a specimen sent from the British Museum to the Australian Museum as *Ceratella fusca*, Gray, is really *Dehitella atrorubens*, Gray, from Algoa Bay.

PARIS

Academy of Sciences, August 9.—M. Émile Blanchard in the chair.—On the problem of Gauss concerning the attraction of an elliptical ring, by M. Halphen. Although a clear demonstration of this well-known problem has lately been made by G. W. Hill (Simon Newcomb's "Astronomical Papers," vol. i. 1882), a fresh solution is here proposed, which has the advantage of not requiring the preliminary resolution of an equation of the third degree.—Observations on the oldest sedimentary formations in North-West France (concluded), by M. Hébert. It is shown that the clay-slates of Saint-Lô, which are pre-Cambrian or Archæan formations, were deposited in horizontal layers in a marine basin, which stretched from Wales southwards to Quimper and Alençon, and which was broken only by a few isolated masses of granite and crystalline schists. This oldest of oceanic waters lasted for a long geological epoch, as attested by the thickness of these deposits, and the transformation of the muddy sediment into hard clay-slates. The present vertical position of these rocks, which were antecedent to all animal life, was evidently due to contraction of the terrestrial crust, by which were determined the foldings, faults, and ruptures, and probably the general upheaval of the whole region.—Reply to M. Hugoniot's note on the pressure that exists in the contracted section of a gaseous vein, by M. Hirn. To M. Hugoniot's objection the author replies that he has shown by experiment that the gas flowing through a cylindrical tube into a reservoir, where it becomes very rarefied, falls gradually from the pressure P_0, which it possesses in the gasometer, to a pressure P_x, which is almost exactly that of the rarefying reservoir.—On the velocity of the flow of fluids, by M. Th. Vautier. Having in a previous communication explained his graphic method, the author here shows the process by which he has successfully applied the revolving mirror to the measurement of the velocity of fluids.—Spectrum of the negative pole of nitrogen: general law of distribution of the rays which appear in the bands of the negative pole, by M. H. Deslandres. In the luminous region, which alone has hitherto been studied, the spectrum of the negative pole is accompanied by faint traces of positive bands. But in the ultra-violet region it is prolonged only by a small number of bands, and becomes, so to say, smothered amid the powerful and numerous positive bands. The rays of the band λ 391 are disposed according to the following simple law: The intervals from one ray to another, calculated in numbers of vibrations, are arranged as nearly as possible in arithmetical progression. This appears to be a general law, not merely an isolated fact, as observed by Piazzi Smyth and Herschel between sixteen rays of the green band of the oxide of carbon.—On the temperatures and critical pressures of some vapours in liquids, by MM. C. Vincent and J. Chappuis. In a previous communication the authors announced their researches on the temperatures and critical pressures of two series of gaseous bodies at the ordinary temperature. Here they give the result of their experiments with liquid bodies at the ordinary temperature—the chloride of propyl, the series of the three amines of ethyl, and the two first normal amines of propyl.—Researches on the variations of solubility of certain chlorides in water in the presence of hydrochloric acid, by M. Guillaume Jeannel. From his experiments with the chloride of potassium the author infers that the variations of solubility of this salt are not subjected to the law recently announced by Engel. He arrives at the general conclusion that the solubility of the chlorides precipitated by hydrochloric acid varies in the presence of the acid, so that the sum of the equivalents of water, salt, and acid forming the solution remains constant at the same temperature, whatever be the chloride and whatever be the proportions of the mixture.—Combinations of ammonia with the metallic permanganates, by M. T. Klobb.—Chemical and thermic study of the phenosulphuric acids: paraphenosulphuric acid, by M. S. Allain-Le Canu. This paper is devoted to a fresh study of the three phenosulphuric acids (oxyphenylsulphonic) $C_{12}H_6S_2O_8$.—On the presence of lecithine in vegetation, by MM. Ed. Heckel and Fr. Schlagdenhauffen. The authors' researches confirm the conclusion already arrived at by Hoppe-Seyler and Krætzschmar that this substance, known to exist in many of the animal tissues, is found also in numerous plants.—Note on fine-flavoured brandy distilled from the grape-cake of white wine, by M. Alph. Rommier.—Fresh researches on the axial nervous current, by M. Maurice Mendelssohn. It is shown that the axial current possesses the same physical and physiological properties that M. E. Du Bois-Reymond has discovered in other nervous currents; also that its direction is in the closest relation with that of the function of the nerve.—On the alterations produced in the constitution of the blood by the action of the sulphuret of carbon on the animal system, by MM. Kiener and R. Engel.—On the resistance of the virus of glanders to the destructive action of atmospheric agencies and of heat, by MM. Cadéac and Malet. It is shown that this virus loses its virulence in humours exposed to the open air after complete desiccation; also that it is destroyed rapidly in warm and dry, slowly in cold and moist weather.—On the disposition of the limestone breccias of the Alpujarras Range, Andalusia, and their resemblance to the carboniferous breccias of Northern France, by MM. Ch. Barrois and A. Offret.—On a method of volumetric analysis for the sulphates, by M. H. Quantin.

THE PHYSIOLOGY OF PLANTS

Lectures on the Physiology of Plants. By S. H. Vines, M.A., D.Sc., F.R.S. (Cambridge University Press, 1886.)

IT has already been pointed out in the columns of NATURE that our botanical schools in England are at present leading in great measure a parasitic existence on those of Germany in respect of the text-books which are in common use: translations of the works of Prantl, Sachs, and De Bary are in the hands of most of our students, while the number of manuals from foreign sources will shortly be increased by the publication of others which are in active preparation. However greatly we may admire the works of the above authors, still it is with no small satisfaction that we turn from them to the review of a book which we may well regard as the first-fruits of a renaissance in this country of the physiological branch of the science of botany; and the more so as the production of original text-books may be taken as one important indication of activity in the pursuit of the subject to which they relate. But while receiving this work of Dr. Vines with a hearty welcome, it is to be regretted that, as noticed in the preface, a considerable interval of time has unavoidably elapsed between the printing of the first sheets and the completion of the book: thus one great advantage of original production as opposed to translation, viz. that of being more nearly up to date, is in some measure lost in the present case, and it is to be hoped that the book will, as it well deserves, quickly run on to a second edition in which this defect may be remedied.

Those who have had the advantage of hearing Dr. Vines in the lecture-room would expect from him a clear style, and a skilful arrangement of the matter; and these are two of the most prominent characteristics of the work before us. Its scope is not that of a manual for mere beginners; it is rather constructed to meet the requirements of advanced students, and accordingly the author is freed from the *impedimenta* of external morphology and anatomy, a sufficient knowledge of which he presumes to have been acquired from other sources. But notwithstanding this presumption, the introductory lectures open in a manner easily followed by the uninitiated, and the whole could be read with advantage by any one who has become acquainted with the mere rudiments of vegetable anatomy.

The first three lectures are devoted to the structure and properties of the vegetable cell, including the osmotic and optical characters of its parts; this is preparatory to the study of the absorption of water, of the substances in solution in it, and of gases, which occupies the two following lectures, this subject being followed in fitting sequence by a discussion of the movements of water in plants, and transpiration. Lecture VIII. is devoted to the constituents of the food of plants, together with the more salient points as regards the functions of the several elements, and the sources from which they are obtained; in this, as in other parts of the book, a short historical sketch is given of the development of knowledge and opinion regarding each several function. Then follows the subject of "metabolism" in its widest sense, a broad distinction being drawn between constructive metabolism, or the building up of the organised structures of plants, and destructive metabolism, or the conversion of more complex substances into others of simpler composition. It is in the treatment of the constructive metabolism that the most striking novelty will be found by English readers, in the introduction of a view regarding the formation of non-nitrogenous organic substance, which, though propounded some years ago in Germany, has now we believe, appeared for the first time in an English text-book. While allowing that starch is the first *visible* product of the constructive processes, the question is asked whether the starch which appears in the chlorophyll corpuscles of a green plant under the influence of sunlight is *directly* connected with the decomposition of carbon dioxide which goes on in them? The answer is as follows (p. 145):—". . . according to Schmitz and Strasburger and in harmony with the older statements of Pringsheim, the cell-wall is produced by the actual conversion of a layer of protoplasm, and we shall see hereafter that the same is asserted of the layers of the starch-grains found in seeds, tubers, &c. Translating this into chemical language we find it to mean that molecules of protoplasm may undergo dissociation in such a way as to give rise to molecules of carbohydrate among other products. The conclusion to be drawn is, that the starch which is formed in chlorophyll corpuscles under the influence of light is also the product of such a dissociation of protoplasm." . . . Both here, and more definitely on p. 158, this point is accepted as proved, and is repeatedly referred to in the treatment of constructive metabolism. But, it will be asked, is it at all admissible thus to "translate" microscopical observations into chemical language? When it is remembered that we do not yet know the constitution of the molecule of protoplasm, that the protoplasm of a living cell is confessedly a most complex mixture, and that the observations quoted demand powers approaching the limits of microscopic observation, it would appear that this "translation" is little more than a figure of speech; that the process is *probably* as Dr. Vines describes it many will be found to admit, but it cannot be allowed that the evidence adduced by him is even a near approach to demonstration. This is not the only case of accepting a probability as a proved fact; thus on p. 174 we read:—"Seedlings, it is well known, contain considerable quantities of amides, and the presence of these can only be accounted for by regarding them as having been derived from the reserve proteids of the seed. It is then in the form of amides that nitrogenous organic substance is supplied to the seedling."

English readers will have become familiar with the view of Pfeffer and Draper that it is the yellow rays of the spectrum which are most efficient in the process of assimilation; and it will be a new idea to many that the balance of experimental evidence is rather in favour of the view of Lommel and others, more recently supported by the observations of Engelmann, that those rays which are absorbed by chlorophyll, viz. the red and violet rays, are the chief source of the energy which becomes latent in the process of formation of organic substance in green plants.

It is impossible within the limits of a short notice to take up more than these two points, but they will be sufficient to indicate that the part of the book which treats of metabolism contains much that is new to English readers both in view and in observation. At its close (p. 326) the results acquired are summarised in tabular form, constructed so as to appeal to the eye as a balance sheet, which takes account of income and expenditure of matter and energy, first in green, and then in colourless plants; this brings out clearly the conclusion that there is a nett balance in favour of the plant in either case, of both matter and energy.

The next section of the book (Lectures XV.–XXI.) opens with a description of the fundamental phenomena of growth, which is a clear statement of facts for the most part already familiar. This leads to a discussion, extending over four lectures, of the accompanying phenomena of irritability of growing organs, which result in their varied directive curvatures; two further lectures are devoted to the irritability of mature organs, considered in the light of the observations of Gardiner and others on the continuity of protoplasm; and the book closes with three lectures on reproduction; these include first an account of the chief types of both sexual and vegetative reproduction, and conclude with a discussion of the theories of sexuality of Strasburger, Naegeli, and Weismann.

With regard to the use of terms, two points demand notice: first, as to the words "dorsal" and "ventral," which have so often been the subject of discussion, especially because of the ambiguity arising from their different mode of application to leaves, and to dorsiventral shoots. But is it necessary to use the terms at all as applied to leaves? Will not the terms "anterior" and "posterior" convey the idea just as well, the terms "dorsal" and "ventral" being thus left free for application to dorsiventral shoots? Secondly, Dr Vines has not accepted the term "zygote" proposed by Dr. Strasburger as generally applicable to the fertilised ovum: this term is of use in avoiding the terms "zygospore" and "oospore," which, especially the latter, are often understood in an ambiguous sense.

To say that Dr. Vines's book is a most valuable addition to our own botanical literature is but a narrow meed of praise: it is a work which will take its place as cosmopolitan; no more clear and concise discussion of the difficult chemistry of metabolism in the plant has appeared, while the part which treats of irritability is an able digest of the voluminous, one might almost say inflated, literature on this branch of the science. In estimating the value of the book as a whole, we must bear in mind the circumstances in which physiological botany is at present placed. There is no branch of biological science upon which it is more difficult to write; our position with regard to the phenomena of vegetable life is throughout based rather upon a calculation of probabilities than upon clearly established facts; it is for each individual teacher in the exercise of his duty to draw a line between the discussion of views, and the acceptance for teaching purposes of points still *sub judice* as though they were established truths. Dr. Vines has gone rather further in the acceptance of probabilities than some will be prepared to follow him, and it is perhaps to be regretted that this should be the case in a book intended for the advanced rather than the elementary student. Placing this on one side, the book is one which must command admiration; a glance at the lists of references at the end of each lecture will give a clue to the extent of the literature which has been searched through; in erudition it stands alone among English books on the subject, and will compare favourably with any foreign competitors.

F. O. B.

A PLEA FOR THE RAIN-BAND

A Plea for the Rain-Band, and the Rain-Band Vindicated. By J. Rand Capron, F.R.A.S., and F.R.Met.S. (London: Edward Stanford, 1886.)

A NEAT little spectroscopic book, and furnished, as all such books should be, with a nice index, as well as not a few plates, which may be considered a second, or graphical, index of an instantaneous reference kind. But further it is both an honest, and a modest, production; for while it says nothing more on its title-page than what it fulfils, it has not cared to introduce there a compliment which it might have most legitimately claimed.

How often in literary history have not two words decided whether a book shall be bought and read, or not: these words being "second edition." But here they might have been exchanged for third, if not even fourth, edition, or "issue" at all events, for the date January 1886.

Mr. Rand Capron is evidently of a very practical order, and writes for practical men; and as he writes only of what he fully understands, and has abundantly worked at with his own eyes and hands,—he has the faculty of pleasing and satisfying those whom he addresses. This is testified to most particularly by the successive reprints of his first pamphlet within the short interval of five years; for though he was not the first and earliest rain-band writer, a public had to be created for the subject, and is evidently now rapidly increasing. This too notwithstanding that the feature wherein Mr. Capron's book is very strong, viz. numerical comparison of rain-band indications in the spectroscope, step by step with rain-gauge measures, or ozone papers, or hygrometrical readings of wet, and dry, bulb thermometers, forms by no means a smooth and easy-flowing kind of reading, as mere reading; however instructive it may be, and even necessary to have at hand to confront unreasoning objectors of an older school; endued often with imperfect senses, but all the more positive in their denunciations of a new departure in meteorology, on that very account.

If the poet is born, and is not to be manufactured by the tutors known in these days of cram as "coaches," so is it most assuredly with spectroscopic observers, when the subject to be observed is not the angular place of a sharp line, but the degree of intensity of a nebulous band of shade like the rain-band. Such intensity too to be determined, not by long and repeated observations with some grand photometrical apparatus mounted on a firm altazimuth stand, with tangent screw motions in every direction, but by a moment's look through a mere waistcoat pocket gem of an instrument held lightly between thumb and finger, and leading instantly to a judgment on the case, like a stroke of nothing less than pure genius.

Yet, by the marvellous aid of the prism with a narrow slit in front of it, there appear to be every year more and more persons who can accomplish the feat, and feel extraordinary satisfaction, even exhilaration, in the act of so doing. Wherefore after reading Mr. Capron's earlier pages, laying down what the rain-band, as seen in the spectroscope, really is, how it is to be observed, recorded, and concluded upon, the percentage of its correctness, and the kind of assistance it may afford to other methods of weather prediction in meteorology,—we have had still more pleasure in coming to his Part II., on "The Rain-Band Vindicated." For therein he describes succinctly the contests which have been recently going on in the meteorological world on the subject, and the rise of many new authors, either bringing in most varied experiences to show the truth of the principle, or still better publishing extensions of it. While from one of Professor Sir Henry Roscoe's earliest works on spectroscopy in general, and the telluric additions to the lines of the solar spectrum in particular,—is extracted this paragraph, which deserves to live.

"No one can tell what secrets lie hid in these atmospheric lines, but to us it seems that by their careful and systematic observation, 'the Message from the Stars' which has taught us so much, may be rivalled in practical importance by a 'Message from the Sky.'"

And the harvest to be gathered is still on the increase; for since the appearance of Mr. Capron's last edition, a new observer in unusually exalted circumstances of temperature, sunshine, and moisture (viz. Mr. Maxwell Hall, in Jamaica), almost at once discovered another rain-band, not in the red, but in the green of the spectrum; and as super-excellent for prediction-use in that tropical island, as our D rain-band in the red is to ourselves at home. What wonder, then, that so able a physicist and astronomer writes, and with such hope and joy too of soon having more leisure to devote to science,—writes, we repeat, that although he has not yet settled the exact line of research he will devote himself to,—it must be "something spectroscopic."

Notwithstanding too that, as yet, the rain-band spectroscope has only been employed by day, in noting the dark, or so-called Fraunhofer, lines and bands on the bright continuous spectrum of the sun-illumined clouds or sky,—there seems a new utilisation of it opening up in detecting aurora, when otherwise invisible, by its unique bright citron line in a dark field at night; and thereby affording men another kind of rainfall prediction, even so much as forty-eight hours beforehand.

In conclusion, though not exactly touching on rain-band, we should call attention to Mr. Capron's appendix, descriptive of his well-arranged and successfully carried out observations on atmospheric electricity, as likely to lead eventually to something practical and exceedingly important. For, as M. Gaston Planté has long held in Paris, he has never yet known a storm of wind which was not accompanied by measurable disturbances of electricity; and with indications that the whole quantity of that fluid, lying latent in the earth, is a store of almost unimaginably large quantity, derived from the Creation Age, and only very slowly escaping; while man is still merely looking on, and unable to turn it to any useful account.

C. P. S.

OUR BOOK SHELF

A Manual of Surgery. In Treatises by various Authors. 3 vols. Edited by Frederick Treves, F.R.C.S. (London: Cassell and Co., 1886.)

MESSRS. CASSELL, in issuing these volumes among their manuals for students of medicine, did wisely in invoking the aid of some thirty hospital surgeons, who have in these three handy volumes produced a very practical work of high excellence.

In comparing such a work as the present with a book on surgery written fifteen or even ten years ago, we are at once struck, on the one hand, by the number of new operations which have been introduced, mainly owing to antiseptic surgery; and, on the other, by the much greater definiteness and accuracy with which diseases and lesions are defined and differentiated from one another. As a consequence, the material is so extensive in amount that operative surgery and pathology will occupy additional volumes.

The relations of micro-organisms to septicæmia, pyæmia, and the treatment of wounds, receive full discussion, extending over several chapters. There is a valuable chapter by Mr. Mills, Anæsthetist to St. Bartholomew's Hospital, on the production of anæsthesia and the means of dealing with the difficulties that may occur.

In the discussion of knee-joint disease a much more favourable view of the benefit of rest is taken than would accord with our experience, and it is stated that with the application of splints the great majority of cases will end in complete recovery in six to nine months. This result, however, is surely uncommon, and too often the pulpy mischief progresses until, after months or years of rest, the patient is able to get about again with a limb liable to lay him up after the slightest exertion, or it has ultimately to be amputated. On the other hand, the permanent good results which are obtained by excision of the knee are much under-estimated, and, instead of falling more and more into disuse, the operation will in the future often be the means of saving limbs that are now amputated, especially when the excellent results that can be shown for a long series of cases have been published.

Abdominal surgery receives ample notice, and in no department during the last ten years has greater progress been made; many injuries and diseases which were formerly necessarily fatal are now amenable to operation. Continental surgeons, able to perform trial operations on animals, are far more successful in their operations on the intestines than we are, and every year human lives are offered up as a holocaust to the fanaticism of the anti-vivisectionists. It is to the physiologists that we are indebted for the elaboration of the various steps by which success is now achieved both in these operations and in those on the brain.

The general excellence of the illustrations, which number 200, is worthy of note; and while many are original, not a few have been selected from other books. There is no doubt that each year it becomes more easy to obtain typical illustrations of disease. We would therefore take exception to the illustrations of the teeth of congenital syphilis, of myxœdema, and of single hare-lip, of which more characteristic examples might have been taken.

The handy form of the volumes, as well as the practical nature of the book, will insure its popularity among students.

L'Évolution et la Vie. Par Denys Cochin. (Paris: Masson, 1886.)

This work, which is a *réchauffé* of the ordinary facts of digestion as given in the text-books, and of the relations of micro-organisms to vital processes, and more especially of Pasteur's work on the subject, must have been written chiefly for the author's amusement. It opens with a pro-

test against Herbert Spencer's application of the principles of evolution to the solution of vital, social, and mental problems. The author then proceeds to set up a ghost founded on the statement made some years ago, that "there is no evolution without spontaneous generation." To refute the theory of spontaneous generation will be, he says, to give a direct blow to the theory of evolution. This, he maintains, has been amply done by Pasteur and others, and a number of the most important experiments are here referred to.

The author proceeds to argue that, since evolution has failed to explain the first beginnings of life, there must have been a God who created matter, a living germ, and an intelligent mind, and that the three creations were distinct.

He gives a clear account of many of the vital as distinct from the non-vital processes, and draws especial attention to the fact that solutions of many of the higher organised products polarise light, and that the only organic bodies which have been formed synthetically are the lower organised products which do not polarise light. It is doubtful, however, whether the distinction is one which will hold much longer, as chemical methods are constantly improving.

The author adduces no new facts, but he has the merit of bringing together in a very readable form, statements more or less scattered about in several books and periodicals.

History of the Royal College of Surgeons in Ireland, &c. By Sir Chas. A. Cameron. (Dublin: Fannin and Co., 1886.)

THIS volume, which is published at the expense and by the authority of the College of Surgeons, collects together the charters and histories of the various Irish Medical Schools and Colleges, and supplies biographies of the leading members of the medical profession in Ireland, together with a list of their works.

Many curious ana are given of the old physicians; among others, of Joseph Rogers (1734), one of the first to feed fevers, who gave a patient daily for a month four to six quarts of sack-whey and two quarts of mulled canary, which was certainly vigorous treatment.

The first Society for the regulation of medicine in Ireland dates back to 1446, when Henry VI. established a Guild of Barbers in Dublin; and later on, in 1572, Queen Elizabeth granted a new charter by which women were admissible to the guild; and in those days a barber was equivalent to our surgeon. This Society lingered on until the foundation of the College of Surgeons in 1784.

This book will be of great use as a work of reference with regard to the state of medicine at any period in Ireland, and its compilation must have been a laborious labour of love on the part of the author. The biographies, which are very numerous, form the most interesting part of the work, and include a large number of world-renowned names, the greatest of which are probably Graves and Stokes.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Physiological Selection and the Origin of Species

As I was unable to be present at the Linnean Society when Mr. Romanes read his paper on the above subject, I may take the opportunity furnished by the publication of the abstract in these columns to put forward certain views which I have long held with reference to the points rai-ed by the author. I may remark that I am writing under the disadvantage of distance from notes or books of reference, and that I have not yet seen the complete paper. Moreover, my work of late years has run off biological tracks, and I can but regret that my remarks must, under the present circumstances, be of a more or less general character; but at any rate they may be of use as a contribution to the discussion which Mr. Romanes' carefully considered paper well merits at the hands of biologists.

In the first place, I should like to point out that evolution by what Mr. Romanes calls "independent variation," or the prevention of crossing with parent forms, is very ably discussed by Weismann in one of his earlier works, "Ueber den Einfluss der Isolirung auf der Artbildung" (1872), which essay I can commend to the notice of all interested in the subject. Weismann termed this principle "*Amixie*," and for want of a better word I have rendered this "Amixia" in my edition of the "Studies in the Theory of Descent," in which work the principle is also frequently alluded to.

All evolutionists will agree with Mr. Romanes that natural selection *per se* is incompetent to account for the origin of species. This has long been admitted by naturalists, and Darwin himself in later life frankly acknowledged that in the early editions of the "Origin of Species" he over-estimated the power of this agency. Nevertheless, Darwin to the last considered natural selection as the *chief agency* in the evolution of species, and no one saw more clearly than he did the difficulties which surrounded the formation of incipient species, owing to the obliteration of new characters by intercrossing with the parent form. The sterility of natural species as compared with the fertility of domesticated races is also a difficulty which Darwin fully recognised and did much towards meeting. The results of his investigations in this direction have been to break down the supposed fixity of the rule, although it must be admitted that the broad fact still remains, and we cannot but be grateful to Mr. Romanes for once more emphasising this difficulty with his characteristic clearness. It is chiefly—if not entirely—with the object of meeting this difficulty that "physiological selection" has been conceived, because, as it appears to me, the other difficulties referred to by Mr. Romanes, viz. those connected with the prevention of intercrossing and the inutility of trivial characters, are quite subordinate to this main difficulty, and need not be further considered until the admissibility (or otherwise) of physiological selection has been settled. The questions now to be decided are whether natural selection + sexual selection + correlated variability + amixia + use and disuse, &c., is really a theory of the origin of *species*, or whether these factors have been only made to "pose" as such? Is "physiological selection" competent to account for the origin of species?

If I interpret Mr. Romanes correctly, his theory is equivalent to the admission that amixia may become inter-racial, *i.e.* that it may arise among the individuals of a species without the intervention of physical barriers by the spontaneous origination of a physiological barrier, *i.e.* by variation in the reproductive capacity. That such a form of variation may exist I have long been willing to admit, and I do so now with all the more readiness in face of the arguments so skilfully marshalled by the author of the new theory. But, since Mr. Romanes admits the efficiency of natural selection, the question seems to resolve itself into this: Can physiological selection work independently of natural selection? If not, natural selection must still be regarded as a prime factor, and if physiological selection cannot originate a species independently of the control of natural selection, surely the latter, with its subordinate factors (of which physiological selection *may be* one), is still *the* chief element in the theory of the origin of species.

Let us suppose, for the sake of argument, that among the individuals of a species there arise certain varieties which are fertile *inter se*, but sterile with the parent form. There would thus arise a new race which could not be swamped by intercrossing with the predominant form, and the one species would practically be resolved into two—the parent form being still in the ascendency as regards numbers. But the competition is always most severe between the most closely related forms, and unless the new form (arising by inter-racial amixia) possessed some distinct advantage over the old one, it would as surely be exterminated by the overwhelming majority of the parent type as it would be by intercrossing in the absence of amixia. Physiological selection thus appears to me to be as subordinate to

natural selection as sexual selection, correlated variability, the law of homology, or any other of the Darwinian factors. The expression used by Mr. Romanes for his new factor—the "Segregation of the Fit"—seems to imply fitness for something, presumably for the conditions of life, and if the survival of the "fit" race is determined by natural selection, then I venture to think that natural selection must still be regarded as *the* theory of the origin of species and as something more than a theory of the origin of adaptations.

To the foregoing Mr. Romanes will probably say that physiological selection is a *necessary* adjunct of natural selection, and that no new species can arise without the co-operation of his factor. If this be the case, then, bearing in mind the views which I have expressed with reference to the subordination of physiological to natural selection, it seems to me that the most likely course to pursue is to appeal to the latter for an explanation of the "primary" specific character, viz. sterility. It is true that Darwin and many of his followers have attempted in vain to account for this primary specific distinction by natural selection, but I still venture to think that the solution lies in this direction. Indeed, the elements of the solution appear to me to be furnished by the original theory of Darwin and Wallace, as I will now briefly attempt to show, hoping to elaborate the idea on some future occasion, or, still better, leaving it for development or extermination in the hands of professed biologists.

The struggle for life being the most severe between the most closely allied forms, diversity is in itself an advantage, because the individuals which depart from the parent type may (but not necessarily *must*) "seize on many and widely diversified places in the economy of nature, and so be enabled to increase in numbers." Hence Darwin's principle of "divergence of character," so well restated by Mr. Romanes in his paper. Now, if diversity is an advantage, natural selection can deal with it like any other advantageous character, and *would seize upon any means afforded to secure its perpetuation*, provided always that the divergence was in the direction of some unoccupied "place in the economy of nature." This last condition amounts to nothing more than that the divergence is to be of an advantageous character. Among the most effectual means of securing permanent diversity must be sterility with the parent form: hence, given a variability in the reproductive capacities of different pairs of individuals (which I have already conceded), the question is whether natural selection could not develop out of this more or less imperfect fertility a more or less complete sterility. If it is to the advantage of some particular variety not to resemble its parent form, out of the immense number of divergences which are always taking place (by ordinary variation) those varieties which showed the greatest infertility with the parent form would in the long run survive, for the very reason that their progeny, tending to inherit the characters of their parents, would possess the advantageous characters of the latter, which led to their survival in the first instance, and, among these characters, that diminished fertility with the parent form which lessens the chance of their extermination by intercrossing.

As the foregoing argument is necessarily expressed in general terms, it will be of use to specialise our ideas by an appeal to a hypothetical case. Suppose, for instance, that a dominant species gives rise to the twelve varieties A, B, C, ... L, out of which four, B, D, K, L, possess some slight advantage over the parent form, adapting them to some new conditions in their environment. The four varieties thus stand a chance of surviving, while the eight others would be the "unfit." Now these four varieties in their incipient stage (and in the absence of isolation) would be subject to extermination by intercrossing in the next generation with the parent form. But the chances against these four varieties being *equally fertile* with the parent form must be exceedingly great: let us suppose, therefore, that B and K are less fertile with the parent form than D and L. Under these circumstances the latter would be wiped out by intercrossing, while the former would tend to retain their peculiarities and thus survive. The peculiarities both of B, K, and D, L, were originally advantageous, but those of B, K, are alone allowed to survive. The parent species has, as it were, attempted to give rise to four derived species, and has only succeeded in producing two. It is a case of selecting out of a number of advantageous modifications those particular varieties which are the least fertile with the parent form. From the slight sterility thus produced in the initial stages, natural selection, by acting in the same direction, might evolve the more or less perfect sterility which we now behold, because every departure on the part of the derived form in the direction of fertility with the parent form would be a retrograde step tending to obliterate those advantageous characters which led to the first survival of the new form, and the descendants of such partially fertile departures would constantly be weeded out owing to the dilution of their peculiarities with the less advantageous characters of the parent form. To put the case in another way, it may be said that natural selection is constantly endeavouring to develop the most advantageous modifications of every species, but succeeds the better the less the degree of fertility of the advantageous modification with the parent form, and succeeds only perfectly by producing perfect sterility with the parent form. Fertile advantageous modifications, on the other hand, would be swamped by absorption into the parent form.

I thus venture to think that the theory of natural selection as sketched out by Darwin and Wallace is still a theory of the origin of species. The production of the sterility of species by this agency is, according to the present views, to be referred to the same causes as all the other modifications produced thereby, viz. the natural selection of a "spontaneously" occurring variation in the function of one particular organ. In the case of domesticated races no such selection with reference to the functions of the reproductive system has been effected, but the varieties have only been kept from interbreeding by what amounts to isolation. It is not surprising, therefore, that such artificial forms, which have been selected only with reference to *external characters*, should be fertile *inter se*, while natural species, in which fertility *inter se* has been rigorously suppressed by natural selection through long series of generations, should exhibit a greater or less degree of sterility.[1] In other words, "physiological" appears as one particular phase of natural selection, and as far as we can see there is no reason why there should not be other modes of variation leading to the same result by acting indirectly upon the reproductive system. But all such modes of variation would still be subject to development or suppression by natural selection. R. MELDOLA

Greenock, August 21

THE Duke of Argyll's letter about organic evolution, published in your last week's issue (p. 335), calls for a few remarks, as it is very misleading, and bespeaks some misconceptions on the part of the writer. He has evidently read his own views into the two articles on organic evolution contributed by Spencer to the April and May numbers of the *Nineteenth Century*. In those articles Spencer makes no "admission"; what he says there with respect to natural selection has been held by him for the last twenty-six years. He does not deny that the natural operations denoted by natural selection do constitute an operating cause in the evolution of species. Only, he goes deeper: he, with his characteristic truly philosophic insight, sees in natural selection a *proximate* cause; sees behind it the primordial operations of forces of nature which rendered natural selection possible, and supplied it with a *point-d'appui*. Then he assigns use and disuse as another cause in the origination of species. Now all this is not a "declaration against" what your correspondent pleases to call "Mechanical Philosophy," but is a part and parcel of it. It is rather a "declaration against" all sorts of teleological philosophy. Let him remember also that Spencer's philosophy is the acknowledged philosophy of evolution; and he may rest assured that, even if the theory of natural selection *as a cause* in the genesis of species be proved untrue, that philosophy will still stand opposed to any philosophy that will attempt to bring back "Mind" as one of the *causes* of organic evolution.

Your correspondent is a little too hasty in his rejoicings over Mr. Romanes' paper on "Physiological Selection." He will see from the s cond part of the paper that even Mr. Romanes is unable to deny that in some cases at least natural selection is quite competent to originate species.

Then your correspondent thinks the theory of natural selection "not only essentially faulty and incomplete, but fundamentally erroneous," "in so far as it assumes variations to arise by accident." Now by "accident" or "chance" in this connection, evolutionists (including Darwin) have simply meant the action

[1] From the above it follows that local races or species produced by isolation should be more or less fertile with the parent form. This is a point which might well be tested experimentally.

of some bidden physical causes whose exact mode of operation is not known. We all know, however, that variations are *facts* of nature, and it is not difficult to see that they are the necessary consequences of the varying number, amount, proportion, and manner of action, of the natural forces acting on different portions of living matter. Now, in making variations the starting-point, the theory of natural selection may justly be considered to be "incomplete," even as our knowledge of electricity is incomplete because we do not know the real nature of the thing, as astronomy is incomplete because we do not know for certain how, for instance, the solar system was formed; but in so doing the theory cannot be "essentially faulty" or "fundamentally erroneous." It is illogical, not to say childish, to think a theory to be erroneous because it cannot render a definite explanation of some unquestionable facts of nature on which it is based and with which it starts. To prove the theory of natural selection to be erroneous, it must be shown that it is never competent to originate species. If it ever falls, it will fall quite *ir*respectively of its avowed inability to give definite explanations as to the exact mode of occurrence of variations. S. B. MITRA

19, Keppel Street, Russell Square, London, August 17

Red Sunsets and Volcanic Eruptions

PROF. S. NEWCOMB'S article on the above subject in NATURE of August 12 (p. 340) induces me to send you a brief account of the atmospheric phenomena that I observed in Palermo during and after the recent eruption of Mount Etna.

This volcano is 133 kilometres distant from Palermo, but the transparency of the air here is so great that it is almost always visible from this Observatory.

At dawn on May 21 the smoke from the eruption appeared as a great mass of black vapour, rising from the southern side of the volcano. At 11 a.m. it had formed into rosy balls of vapour, or cumuli. With the theodolite I measured the angular height—2° 21′, which gives 8 kilometres of linear altitude. On May 24 the smoke had the characteristic form of a pine-tree, and a greater height, but at 4 p.m. the upper edge of it was not well defined, and I obtained (approximately) the altitude as 14 kilometres.

Since May 22 these vapours from Etna have spread over the eastern, and more recently over the entire, horizon of Palermo. In the early morning of June 3 the fog was so dense that the sun was invisible, and the towers of the Matrice, 200 metres distant, were only indistinctly visible, which in Palermo is quite extraordinary. From May 29 to June 3 Italy has been invaded from south to north with mist, which was probably also derived from Etna.

Cinders from the volcano have fallen over Eastern and Southern Sicily, and over Calabria, as well as in Palermo, where, in the dust gathered on the terraces of the Observatory on May 27, I detected with the microscope some minute crystalline laminæ of labradorite, which mineral is characteristic of the ejections of Etna.

The sun rising from the sea behind these mists has been purple-red and then reddish-yellow; at a height of about 30° it was neutral gray, but never green or blue. In Nicolosi, too, on the side of the volcano, these colours of the sun have not been observed. The light of the red sun was so faint that it was possible to look at it without inconvenience.

No corona (like "Bishop's ring") was observed around the sun or moon. Spectroscopic observations of the red sun gave only the ordinary atmospheric absorptions, perhaps somewhat intensified.

In the latter part of May and during the month of June the red after-glows appeared almost daily, and were stronger than before or since, but they were not so brilliant and prolonged as in 1831 and 1883–84, and their colour was not properly rosy, but an impure reddish-yellow.

I believe that the red sun was caused by the finest cinders from the volcano, suspended in the air, as the like phenomenon is produced by the dust of the Höherauch in Northern Europe, of the Sirocco in Sicily, and of the Kamsin in Africa. The blue sun (observed after the eruptions of Ferdinandea and of Krakatão) has not appeared, and the after-glows were not strongly brilliant, because the vapours ejected from Etna were not so enormously abundant as those ejected from Ferdinandea and Krakatão, which are marine volcanoes more directly communicating with the water of the sea.

The observation by M. Janssen, mentioned in NATURE of July 29 (p. 299), of a blood-red coloration of light traversing dust, gives a strong confirmation to the preceding explanation of the red sun. A. RICCO

Palermo Observatory, August 17

P.S.—Since July Bishop's ring has not been visible in Palermo.

The Bright Clouds and the Aurora

ON the morning of the 11th inst. I had an opportunity of watching the curious cirrus-like clouds as daylight came on. The display was striking, though not such a bright one as on several former occasions. It first appeared about 2.30 a.m., when there were very faint indications of the clouds; it was some minutes before I noticed that they were the same brilliant kind as has appeared so often this summer. Their apparent upper border being irregular, it was uncertain whether they in any part reached the limit to which the sun could shine upon them, or whether the apparent border was altogether the actual edge of the cloud-sheet; however, it rose higher as the sun approached the horizon, but this might be owing to the circumstance that the motion of the clouds was, as usual, from an easterly direction. At 3.33½ a.m. they were visible as far as α Andromedæ, though they were very faint west of γ. By 3.45½ a.m. they reached down to within 5° of α Aquilæ, and were rather plain there, and by this time the sheet covered most of the sky, though none of it remained visible very low down in the east. It was no longer bright in any part. At 3.55½ they reached down to within 4° of α Aquilæ, and were plainest about there, but growing fainter. I was still uncertain whether the sheet extended beyond the western apparent border, that being simply the limit of sunshine, or whether the sheet ended there; but probably the former was now the case. At 4 a.m. they were scarcely noticeable, and by 4.11 they had disappeared altogether. By this time a faint pink glow had appeared in the east.

The question is, Was the disappearance of the clouds due to their having evaporated, and ceased to exist, or to their light being overpowered by the brightness of the sky? It appeared to me that the latter was the case. It will be well if further observers can confirm this supposition or otherwise; if correct, they cannot be considered clouds at all in the ordinary sense, the sky being beautifully clear and blue after they had ceased to be visible. I could not say at any time that the clouds were not perfectly transparent to the stars. The circumstance that they have never been described as having been seen by day seems confirmatory of the above supposition.

With respect to Prof. Smyth's remark about the spectrum (p. 311) I do not gather whether he considers that the auroral line noticed by him belonged at all to the clouds or entirely to the aurora; but I think that there can be no doubt that the latter was really the case. He does not seem to have detected any aurora at the spot where the clouds were seen, but doubtless it was there, although overpowered by their brightness. As it is so evident that these clouds were illuminated by the sun (this being confirmed by their varied colours depending on their altitude, as described by Prof. Smyth), we cannot expect their spectrum to be otherwise than solar and atmospheric. I looked at them with a miniature spectroscope on the evening of July 12, as well as on the morning of the 11th inst., but on neither occasion was the spectrum bright enough for me to perceive much. I could not see any lines, bright or dark, but the spectrum faded very abruptly in passing from green to orange, which no doubt was owing to the atmospheric bands near D, especially the "low sun band."

On July 27 I saw the aurora mentioned by Prof. Smyth at Gilsland, in Cumberland, and it was a particularly magnificent one there, especially about 10.25 p.m., at which time a part of it was lilac—a very unusual colour. The bright clouds were also visible that night, but chiefly before the aurora appeared and after it vanished; there appears no reason to suppose there is any connection between the two phenomena.

As regards the dark space beneath the auroral arch, has the theory mentioned by Prof. Smyth ever been proved, that there is any true darkness there, and that it is not merely the effect of contrast with the aurora? My impression is that it must be at least mainly the effect of contrast, though perhaps not entirely, and the idea is confirmed by a similar darkness sometimes appearing by contrast with the brilliant clouds, when no

aurora is present; the stars shine quite bright in this dark sky above them.

Prof. Smyth considers that the night after the aurora of the 27th the twilight extended over the region "aurora-blackened" the evening before. Would not this be owing to the brightness of the aurora preventing the twilight from being seen so high then simply by contrast? The fact that the dark sky was luminous in the spectroscope seems to bear out this.

I do not understand Prof. Smyth's suggestion why these clouds should never be seen in winter, for any night in the year there is a time when the sun is at the same distance below the horizon as it is when the bright clouds are well seen.

Sunderland, August 18 T. W. BACKHOUSE

Cloud Effect

A VERY unusual cloud effect was noticed here on the 18th inst. at 7.45 a.m. The whole sky, especially to the east or south-east, was at that time covered with a widespread field of mackerel cloud. This field was cut from north to south with a strongly defined cleft or narrow line showing the blue sky beneath. It was like a crack in the cloudy tissue, and formed a perfect arch, whose greatest altitude was not many degrees above the sun's apparent place. It lasted nearly half an hour. There was little wind at the time, only a slow motion from the north, but a change took place shortly after, when it veered to the south-west. E. BROWN

Further Barton, Cirencester, August 20

The Crag Deposits on the North Downs

To students of Tertiary geology, the interest of Mr. Clement Reid's verification of Prof. Prestwich's judgment of many years ago as to the Pliocene age of certain outlying deposits at Lenham is so great that I must crave permission for space for a line or two with reference to other similarly situated deposits on the North Downs, which have been described as belonging to an horizon "somewhere between the Chalk and the moon." The deposits to which I refer were described by Prof. Prestwich in the *Q.J.G.S.*, vol. xiv., and of his paper Mr. Whitaker made free use in preparing the account of these outliers in vol. iv. of the "Memoirs of the Geological Survey" (pp. 336 42). The idea has been for some time growing up in my own mind, with reference to these unfossiliferous outliers, that some of them will have to be recognised as remnants of the once more widely extended Upper Bagshot Sands. This conclusion is at present based mainly on three facts: (1) the literal application of Prof. Prestwich's description of their lithological character to portions of those beds; (2) the occurrence of "similar beds on the Chalk Downs on the opposite side of the Channel, between Calais and Boulogne"; (3) the superposition of "analogous strata" on the top of Cassell Hill in French Flanders upon the *Calcaire grossier* series, the equivalent of our Middle Bagshot (so-called Bracklesham) Beds. I hope to deal with this more at length during the next session of the Geological Society, and only draw attention now to the suggestion which I threw out several years ago (*Proceedings* of the Geological Association, vol. viii. p. 170) for reasons assigned, that the oldest plateau-gravels of the London Basin are probably of Pliocene age. This may possibly have escaped Mr. C. Reid's notice. A. IRVING

Wellington College, Berks, August 17

Actinotrocha on the British Coasts

IN answer to Mr. Cunningham's letter on the distribution of Tornaria and Actinotrocha, I may state that I took Actinotrocha in the tow-net at the mouth of this bay on July 31. I believe I have found it more than once before on the west coast during the last few years, but, not having my note-books with me, I cannot say definitely where and when. If I am not mistaken, *Phoronis* was found by Dr. Strethill Wright in the Firth of Forth, and is therefore known as a British animal.

Loch Ranza, Arran, August 21 W. A. HERDMAN

GEORGE BUSK, F.R.S.

A SINGLE-MINDED, true-hearted man, a warm friend, and an able and accomplished naturalist, has just passed away from the midst of his family, his friends, and his fellow-workers.

George Busk was the second son of Mr. Robert Busk, of St. Petersburg. He was born in 1807, and at an early age gave promise of those tastes and of that aptitude for research which, developing with his years, gained for him the high position which he was destined to hold among the scientific workers of his time.

After completing his medical education he was appointed surgeon to the seamen's hospital-ship *Dreadnought*, a post which he continued to hold for about twenty-five years. It is these twenty-five years which constitute the strictly professional period of his life, and which gained for him a place among the most distinguished members of his profession as an able, clear-sighted, and enlightened surgeon.

In 1856 he resigned his appointment to the *Dreadnought*, and at the same time decided on retiring from professional practice and on devoting himself to scientific work.

Having now leisure for the cultivation of those studies which were always dear to him, he threw himself warmly into biological work. An excellent and cautious observer, it was chiefly to researches on the structure of the lower members of the organic world that he now devoted himself, and scarcely a month passed without the periodical literature of biology receiving from his labours the record of some new and interesting fact.

About this time he became one of the editors of the *Microscopical Journal*, and the numerous communications which appeared from his pen in the pages of that periodical contributed largely to its popularity and success.

There were few departments of biological science which Busk did not enrich by his researches, and we now find following one another in rapid succession a long series of papers containing the results of his studies among the lower groups of the animal and vegetable kingdoms. He was a skilful microscopist, an acute and conscientious interpreter of the optical expressions of organic form presented by the microscope to the observer, and his contributions to the transactions of our leading scientific societies and to various natural history journals have advanced our knowledge of some of the simple unicellular plants, of the Infusoria, the Hydroida, the lower Vermes, and above all of the Polyzoa, to an extent which those who have worked in the same fields can fully appreciate.

In 1856 appeared his article "Polyzoa" in the English Cyclopædia. In this admirable article we have an exhaustive account of the structure of the Polyzoa, while it contains the first satisfactory attempt at a scientific arrangement of the group, and proposes for the first time the employment of certain systematic characters which are now universally accepted as offering the only legitimate bases of a philosophical classification.

Soon after this he undertook the labour of drawing up an illustrated descriptive catalogue of the Polyzoa contained in the collection of the British Museum, and brought to bear on the descriptions and systematic arrangement of the species those principles whose soundness he had already established. There was thus placed in the hands of the student a work of great value, with which no investigator of the group can afford to dispense.

On the return of H.M.S. *Rattlesnake* from its explorations in the Australian seas under Capt. Owen Stanley, the collections of Polyzoa and Hydroids made during the voyage were placed in Mr. Busk's hands for examination and description. His report on the new species thus obtained is published in the narrative of the voyage, and forms an important addition to our knowledge of these animals.

Among the facts of anatomical interest which have been successfully worked out by Busk in the organisation of the Polyzoa, his demonstration of the structure of the *avicularia* and *vibracula* deserves special mention. He has given by far the best account which had been hitherto

published of the structure and functions of these remarkable and enigmatical bodies, while he insists on their value in affording characters for classification. His very instructive and expressive figures form part of the illustrations of Polyzoal morphology contained in the morphological atlas of Victor Carus.

It was about this time that Busk undertook, for the Palæontographical Society, a monograph of the fossil Polyzoa of the Crag,—a task for which his knowledge of the recent species had eminently fitted him. But his geological work was by no means confined to researches among these lower forms of life. In 1864 he made a journey to Gibraltar along with Dr. Falconer, for the purpose of investigating the ancient fauna which had been preserved in the caves of that region. The results of the joint labours of the two explorers were embodied in a report read at the Norwich Meeting of the British Association in 1868, and more fully in a complete monograph on the subject subsequently published. Among other palæontological contributions may be mentioned his observations on certain points in the dentition of fossil bears, as affording good diagnostic characters, and on the relations of *Ursus priscus* to *Ursus ferox*; also his descriptions of three extinct species of elephant, the remains of which were collected by Capt. Sprat in the ossiferous caverns of Zebbung in the Island of Malta; his report on the animal remains in the Brixham Cave; and a report on the animal remains found by Col. Lane-Fox in the High and Low Terrace-gravels at Acton and Turnham Green. All these communications bear evidence of his skill in recognising palæontological characters and in detecting their relations with those of living forms, while his study of fossil mammals, and his comparison of these with existing species, suggested to him an ingenious method of graphically representing the dimensions and proportions of mammalian teeth.

It was somewhat later than this that his attention was largely given to ethnology, and the Anthropological Society not only owes to his pen many valuable memoirs, but bears evidence of judicious management and administrative capacity in his labours as its President and as a member of its Council. Along with Dr. Carpenter and Dr. Falconer he formed one of a Commission which visited France in order to take part in the Conference which was held there for the purpose of inquiring into the circumstances attending the asserted discovery of a human jaw in the Gravel at Moulin Quignon, near Abbeville. Among his other anthropological work will be found many interesting comparisons of crania belonging to various nations. These investigations were carried on chiefly by means of a systematic method of measurement, which he advocated as affording a uniform basis of comparison, by which anthropological studies might be facilitated and the data of comparison rendered more definite and precise.

At a time when the German language was much less understood in this country than it is at present, Busk performed an important service by giving to the English student an excellent translation from the German of Steenstrup's famous treatise on the alternation of generations, and, in collaboration with Huxley, a translation of Kolliker's valuable manual of human histology.

The last piece of work which devolved on him was the preparation of a Report on the Polyzoa collected during the voyage of the *Challenger*. The first part of this important work was completed in 1884, and has been already reviewed in NATURE. It forms an admirable exposition of the additions made to our knowledge of these animals by the great exploratory voyage; and amply realises all that had been expected from one who had made the Polyzoa the subject of so much careful and philosophic study.

The second and concluding part of the Report he left behind him in a condition nearly ready for the press, and under the judicious supervision of the proofs by his eldest daughter—through whose loving care during his last months of suffering he was enabled to carry on his work to completion—is now quite ready for publication.

The many-sidedness of Mr. Busk's mind was one of the most striking features of his clear and comprehensive intellect, and naturally obtained for him distinctions and honours in many and various departments of science. He was early elected a Fellow of the Royal Society, of which he was afterwards nominated one of the Vice-Presidents, and on the Council of which he served on several occasions. He was more than once President of the Microscopical and Anthropological Societies, was Zoological Secretary of the Linnean Society, and would have been made its President were it not that, notwithstanding the warmly expressed solicitations of the Council of that body, he felt that the labour of the Presidential chair was greater than he believed himself justified in undertaking.

In recognition of the eminence he had attained as a surgeon during the professional period of his life, and of the interest he had always continued to take in the welfare of his profession, he was elected in 1871 to the Presidency of the Royal College of Surgeons. He was one of the Trustees of the Hunterian Museum of the College, and continued for three years to hold in connection with that Museum the Hunterian Professorship of Comparative Anatomy. He was a Member of the Senate of the University of London, for many years Treasurer of the Royal Institution of Great Britain, and had more recently been nominated one of the Governors of Charterhouse School.

For his researches in zoology, physiology, and comparative anatomy the Royal Society in 1871 awarded to him the Royal Medal, while for his palæontological researches he afterwards received from the Geological Society the Lyell and Wollaston Medals.

On the passing of the Cruelty to Animals Act, intended to regulate the performance of experiments on living animals, he was appointed by Government inspector of the various medical schools and physiological laboratories registered under that Act in England and Scotland; and the judgment and skill with which he performed the difficult duties of the office bear ample testimony to the wisdom of his appointment. Abhorring the infliction of unnecessary pain, he saw that for the advancement of knowledge which might tend to the alleviation of human suffering such experiments were not only permissible but called for, while at the same time he set himself strenuously against the infliction of pain which might be avoided, and against the institution of experiments which did not hold out obvious promise of the results which alone would justify them.

He was a genuine lover of Nature, deriving unalloyed pleasure from all that was beautiful in the external world; and the writer of this notice can well remember the enthusiasm with which he would recall the vegetation of the lower reaches of the Thames—amid which his early work on board the *Dreadnought* lay—with its rich growth of Sagittaria, and Butomus, and Sedges, and picturesque water-weeds, long since swept away before the spread of manufactures and the encroachments of civilisation.

Generous and liberal to his fellow-workers, with his rich store of material always at their disposition, his loss will be long and deeply felt by the many who profited by his friendship. Free from all selfish and personal ambition, and pursuing his investigations for the sake alone of the truths which might result from them, he cared little about asserting his claims to discovery, and would rest satisfied with the belief that, whoever may be the discoverer, human knowledge would be the gainer.

And yet, though he had no ambitious longing for reputation, Busk was no cynic. He could appreciate the esteem of those whose esteem was worth having, and few

men had a larger number of genuine admirers, or gathered around them a wider circle of sincere and attached friends. And not alone to the fields in which he himself worked did he extend his interest and sympathies. Amid the labourers in very different departments of thought he found some of his most cherished friends—frequent and always welcome guests at his hospitable home. For these, and for all who had enjoyed the privilege of his friendship, the sorrow at his loss will be softened by the ennobling memory of his life.

GEO. J. ALLMAN

BRITISH ASSOCIATION, SECTION B: DISCUSSION ON THE NATURE OF SOLUTION

IT may perhaps be convenient to those chemists who have announced their intention of joining in the proposed debate in Section B, at the approaching meeting of the British Association, that, having accepted the invitation of the President to open the discussion, I should indicate briefly the general nature of the subjects upon which I shall offer some remarks, and the order in which I shall probably take them.

After an historical sketch of the theories which have been framed with the object of explaining the constitution of saline and other solutions, the phenomena of solution will be dealt with somewhat as follows :—

Thermal and volume changes occurring in the act of solution and their mutual relations. How far and under what circumstances are thermal and volume changes to be considered as indicating chemical change?

The molecular volumes of salts in solution. The specific heat and vapour pressures of salt solutions. The relation of solubility to molecular volume, to fusibility, and to the composition of the liquid.

Action of solids and especially of porous bodies on solutions. Phenomena of supersaturation.

What is chemical combination, and is there any criterion by which it may be distinguished from adhesion or mechanical combination?

In consequence of the very wide-reaching character of the subject, it will not be possible to take up the question of solution except as relating chiefly to solids, and especially salts, in water. For the same reason I cannot fully discuss the phenomena of absorption-spectra nor generally the action of solutions upon light, but I hope some of those chemists who have worked on this part of the subject will be present, and will give us the benefit of their experience.

There will of course be a great number of questions incidentally touched upon in my opening, which may well form the basis of remarks from other speakers, such as—

How is saturation to be explained, *i.e.* why is there generally a limit to solubility?

Is there any general connection between solubility and atomic weight in a series of compounds in which only one constituent varies?

What becomes of water of crystallisation when a salt containing water is dissolved in water?

WILLIAM A. TILDEN

The Mason College, Birmingham

THE RECENT VOLCANIC ERUPTIONS IN NEW ZEALAND

WE have been favoured by Dr. Hector, F.R.S., Director of the Geological Survey of New Zealand, with a copy of a Preliminary Report drawn up by him for the New Zealand Government regarding the volcanic eruptions of last June in the North Island. It is gratifying to find that the hope expressed in NATURE (p. 322) has been so promptly fulfilled, and that the investigation of the remarkable phenomena has been undertaken by so competent an observer as Dr. Hector. The following is his Report, but it is merely a preliminary outline, and will no doubt be followed by much ampler details.

"*Colonial Museum of New Zealand, Wellington, June* 23, 1886

"According to instructions from Government, I proceeded to Tauranga on the evening of Thursday, the 10th instant, in the colonial gunboat *Hinemoa*, and arrived there on Saturday afternoon. At Tauranga I engaged the services of Mr. Spencer, a skilful landscape photographer, and on Sunday our party, seven in number, drove to Rotorua by the Oripi Road, the ordinary route by Te Puke being blocked On Monday I proceeded to Wairoa with Captain Mair, who joined the boat expedition which had been organised to search the Native settlements on Tarawera Lake. On the same day I sent my assistant, Mr. Park, to the south of the disturbed area by way of Kaiteriria; and on Tuesday, following the same route, I examined the vicinity of Rotomahana. Mr. Spencer, with his camera, accompanied me everywhere, so that a series of well-selected views of the eruption and its effects was obtained. On Wednesday we started for Taupo, feeling anxious to complete the general view of the whole line of volcanic activity from Ruapehu to White Island, as alarming rumours were in circulation as to the extent of country that had been affected. By this route we also obtained a distant but interesting view of the newly-raised cones of Tarawera from the eastward. The incidents of the eruption have been so fully described by the Press that it is unnecessary for me to refer to them in this preliminary report, the chief object of my rapid inspection having been to ascertain the exact locality, nature, and extent of the outbreak, and its probable consequences to the district. A complete geological examination of the district has therefore been deferred until a more favourable season for field-work, and until the volcanic activity has sufficiently subsided to admit of accurate observation.

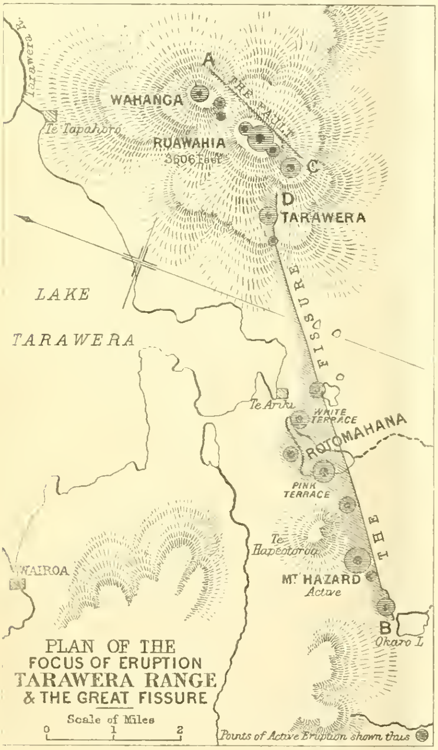
"The focus of the disturbance was ascertained to be in a line extending from seven to ten miles in a north-east to south-west direction from the north end of the Tarawera Range to Okaro Lake (see plan.) The northern part of this line is occupied by the Tarawera Range. This range has three summits, the northernmost being Wahanga; the central, Ruawahia, 3606 feet alt.; and the southernmost, Tarawera Mountain proper. The southern part of the line previous to the outburst was a depression occupied by Rotomahana Lake, surrounded by low undulating country composed of pumice-sands and overspreading deposits of siliceous sinter, most of which were connected with active geysers, amongst which the most famous were those at the Pink and White Terraces.

"From the most reliable evidence it appears that the outbreak commenced at ten minutes past two on the morning of the 10th, by an eruption from the top of Wahanga, attended by a loud roaring noise, and slight earth-shocks. In a few minutes this was followed by a similar but more violent outburst from the top of Ruawahia—the middle peak of the range, and after a short interval this phase of the eruption culminated in a terrific explosion from the south end of Tarawera Range, north-east of Lake Rotomahana. For nearly two hours this was the only phase of the eruption, and was accompanied by the ejection of vast quantities of steam, pumice-dust, and hot stones, forming huge towering clouds, illuminated by lightning flashes.

"It was at this time also that a great crack or fissure (A C on plan) was formed along the east face of the Tarawera Range. I only had a distant view of this fissure from the eastward, but Mr. Percy Smith, the Assistant Surveyor-General, who had a near view from the sides, reports that the whole east end of the mountain

has been blown away, and that the *débris* covers the country to a distance of many miles. The white terrace of pumice-sand that I saw was singularly flat-topped, and seemed to slope abruptly from the mountain like a huge embankment 500 feet high. Besides these heavy sands that lodged close to the fissure in the mountain side, the lighter dust was spread out in the form of stratified clouds, which were distinctly seen, at this period of the eruption, from Rotorua, Tauranga, and Taupo.

"The cloud thus formed discharged its contents for the greater part in a direction to the eastward of the mountain, reaching as far as Te Teko and Fort Galatea, and to the westward as far as Wairoa. The earth-shocks, however,



PLAN OF THE FOCUS OF ERUPTION TARAWERA RANGE & THE GREAT FISSURE

Stanford's Geog¹ Estab^t

during this period of the eruption do not appear to have been of extreme violence, or to have created much alarm beyond that part of the district lying in the immediate vicinity of the volcanic eruption; but shortly before four a.m. a violent outburst of a totally different nature was experienced, accompanied with loud reports that reverberated through the atmosphere to enormous distances. The first notice of this outbreak was an earth-shock that appears to have been much more widely felt than those previous, and chiefly in areas where hot springs occur. This development was attendant on the outburst of an immense volume of steam—carrying pumice-dust and fragments of rocks to an enormous altitude—which proceeded from the site of Rotomahana Lake, causing the formation of a dense cloud in the higher atmosphere, that spread in definite directions, its advancing edge being marked by electrical discharges of the most awe-striking character. At first the wind was from the south-east, and the inhabitants of Rotorua appear to have been terrified by the approach of this hideous cloud, when suddenly the wind sprang up from the south-west and arrested its progress in that direction, turning it off towards the north-east, at the same time condensing the vapour of the cloud to such an extent that the suspended solid matter dropped on the surface of the earth in the form of mud, smothering the country, and leading to the disastrous results experienced at Wairoa. By six a.m. the period of active eruption appears to have closed, and since then the display of energy in a modified form has also rapidly declined.

"The following are the chief points which require notice in this report:—

"I. *Focus.*—Tarawera Range, about 3600 feet above sea-level, is an isolated and very conspicuous object in the scenery of the Lake District. It slopes from the east side of Tarawera Lake—the level of which is about 1000 feet above the sea—and previous to the eruption rose very abruptly, with mural precipices and columnar rocks, especially on its western and southern escarpments. It was no doubt judging from this feature that Dr. Von Hochstetter was led to class Tarawera Mountain with the Horohoro Range, as being part of his older or submarine-formed volcanic series, and a remnant of the great plateau (Von Hochstetter, "Reise der Novara," i. 106), the surface of which denotes the original level of the country prior to the production of its present broken surface by the excavation of valleys, by the up-bursting of volcanic mountains, and the consequent subsidence or breaking-in of large cavities that are now occupied by lakes. He nevertheless maps Mount Tarawera as belonging to his recent volcanic group, and also alludes to it in other parts of his work as being largly composed of obsidian. I have never ascended the Tarawera Range, but have examined its slopes and found them to be composed of lavas of a high acidic or rhyolite type, in the form of flows intersected by dykes, and containing, amongst other rocks, large quantities of compact and vesicular obsidian. From this I conclude that the mountain really is one of recent volcanic origin, belonging to Von Hochstetter's new volcanic series, and that its abrupt outlines have resulted from fractures and subsidences of its flanks. According to this view it is natural to assume that the still-imperfectly-cooled mass of lava in the heart of this volcanic mountain has given rise to the long-continued (historically speaking) solfatara action at high temperatures that created the attractive wonders of the Rotomahana. It has been stated that no Native tradition exists of Tarawera having been the site of previous activity, but the range culminates in three distinct peaks, the meaning of the Maori names of which—according to Mr. Locke, M.H.R., and other authorities—clearly contradicts this assumption. This consideration has interest, as a sudden development of volcanic activity in a new locality, or in an ancient and greatly-denuded formation like the trachyte breccia that forms the Horohoro, would have been more serious and significant than the mere temporary revival of the expiring energies of a recent focus of volcanic force.

"II. *The Vents.*—As viewed across Rotorua Lake, on the 13th, from the point where the Tauranga Road emerges from the bush, Tarawera Range appeared to have quite lost its former characteristic outline. The deep gap dividing Wahanga, the northern peak, from Ruawahia, the central one, was almost obliterated, and the abrupt, precipitous sides of the mountain were everywhere softened by great slope deposits of material ejected from the volcanic vents, consisting of stones and dust of a grey colour. Along the edge of the range seven distinct

points were seen to give off steam from flattened conical heaps of dark-coloured *débris*, and at intervals these vents threw off large volumes of steam and vapour, darkened to a reddish hue by solid matters, which were discharged to a height estimated at from 200 feet to 500 feet. Four days later, when viewed from the eastward, the same range showed a similar appearance, allowing for the change in direction; but the cone on the summit of Ruawahia had evidently accumulated with greater rapidity than the others, and had acquired lateral cones, giving its outline a similar appearance to that of Rangitoto, near Auckland.

"During two clear nights I watched the eruption from these vents, and could distinguish them against the sky with a powerful binocular telescope; but I never observed any illumination of the ascending steam clouds, as if from the surface of an incandescent mass within the vent, nor was there any sign of any outpouring of lava, either from these vents or from cracks or fissures in the sides of the mountain, during the time of my visit. In addition to the above-mentioned conical vents on the summit of the range, along its eastern side the line of fissure already alluded to was distinctly visible, emitting wreaths of steam. This line of fissure lay in an oblique direction, so that it appeared to gain in elevation along the sides of the mountain from north towards south, but not sufficiently so as to indicate for it a direction that would make it continuous with the great fissure south of Tarawera, but rather in the direction of line A C on plan. It is below this fissure-line on the eastern flank of the range that bulky terrace-like accumulations of pumice-sand have been formed, and if this eruption should ever reach the stage of producing lava, which from other circumstances I think hardly likely, it is from this fissure that I should expect the lava to exude.

"III. *The Great Fissure.*—This is the most remarkable and characteristic feature of the late eruption, and the chief origin of the disastrous results which attended it (B D on plan). A good view, but much obscured by steam, was obtained from the hill called Te Hape-o-Toroa—alt. 2300 feet—by Mr. Park on the 14th, and by myself on the following day. This fissure seems to commence as a narrow rift at the northern end from the great rent which has been formed in the south end of Tarawera Mountain. This rent is a most wonderful feature. It is not a slip from the mountain side, but appears as if a portion of the mountain measuring 2000 feet by 500 feet, and 300 feet deep, had been blown out, leaving a ragged, rocky chasm, from which steam was being discharged in rapidly-succeeding puffs. The eastern side of this chasm was brightly tinted, as if by the efflorescent deposit of a mineral substance, probably ferrochlorides. Sulphur has been mentioned as a deposit from this recent outburst by some who have witnessed it; but this is hardly a possible result of such rapid volcanic developments.

"The view I obtained of the extent of this chasm south was much obscured by numerous volumes of steam blowing off from the newly-formed fumaroles that occupied the site of Rotomahana. From the eastern slope of Te Hape-o-Toroa we looked right into the fissure, and, as far as I could see, it appeared to have a nearly straight boundary of undisturbed ground on its eastern side, extending from the Tarawera chasm to within a few chains of Lake Okaro, thus intersecting the Rotomakariri or the cold lake, the Rotomahana Lake, and the valley extending from thence southward. The west side of the fissure, on the other hand, is very irregular in outline, and is continually being altered by the falling-in of its precipitous walls, as the hills are undermined by the action of powerful geysers, seven in number, which at irregular intervals throw up great volumes of boiling water, with stones and mud, to a height of 600 feet to 800 feet from the bottom.

"It is only by occasional glimpses during the breaks of the steam that any idea can be formed of the nature of the bottom of this huge fissure; but it seemed as if it was entirely occupied by large circular areas of mud, seething and boiling in such a fashion as to convey the impression of its being in a very liquid state. These mud-pools are separated from one another by comparatively solid ground, and in some cases, especially towards the eastern side of the fissure, what appear to be small pools of water with sedgy margins could even be distinguished; but the difficulty of estimating distances and depths through the steam-clouds rendered the observations made very uncertain.

"The largest of these mud geysers appeared to be that rising from the position formerly occupied by the Pink Terrace, but the most interesting is one a mile further south, which, unlike the others, does not spring from the bottom, but from the comparatively high ground on the west side of the fissure, and, owing to the obliquity with which the fragments are thrown out, is gradually building up a conical mound, which already has attained an altitude of several hundred feet (Mount Haszard, on plan). At the southern extremity the fissure is bounded by a bold semicircular extremity, from the base of which powerful steam jets are escaping; but there was no evidence that it was prolonged by a crack or fissure, or fault, or other displacement of ground, nor was there any evidence that the fissure had been produced by any inequality of the movement of the ground bounding it, but rather that it was caused simply by the removal of material which formerly occupied its space. Its direction, as far as could be ascertained, is N. 50° E., which is the general line of direction that would connect all the more active geysers between Tongariro and White Island.

"IV. *Matter ejected during the Eruption.*—The quantity of matter which was ejected during the different phases of the eruption was very large. In the first place, stone fragments were scattered from the earlier eruptions of Tarawera over an area of country extending to the eastward as far as Te Teko, and even, some say, to Fort Galatea; while in the opposite direction they are not reported to have fallen at any place farther west than Wairoa, a distance of six miles. None of the fragments which I collected are other than portions of rocks of the district, nor do they present in the slightest degree the character of volcanic bombs or lapilli formed from lava or rock material in a state of fusion. Yet there can be no doubt, if we can accept the evidence of the eye-witnesses, that these rock-fragments must have, in some cases, reached the ground in a partially incandescent state. Next followed the great ejection of pumice-sand, which forms enormous deposits in two localities: the one is on the eastern slope of Tarawera Mountain, already described, the nature and origin of which I had no opportunity of ascertaining; the other deposit of this nature is chiefly on the western side of Rotomahana fissure, and was no doubt ejected at the commencement of the second phase of the eruption. Over a district of twenty-four square miles south of Tarawera Lake, and on an almost equal area to the north and east of the lake, the whole surface of the country has been covered with this pumice-stone so thickly as to obliterate in a great measure the natural features, partly filling the gullies and enveloping all the hills as if with a deep mantle of snow, so that not a trace of vegetation can be seen, from the highest peaks, such as Te Hape-o-Toroa, which is 2300 feet above the sea, down to the level of the lake. The thickness of this deposit could not be ascertained at the time of my visit, as no slips had occurred in it and no sections were to be seen. It consisted of fine-grained and gritty pumice-sand, slightly crusted on the surface by the action of the rain, which also caused it to assume a slightly greyish tinge; but underneath it was a pure white, and at a depth of 12 inches to 18 inches from the surface had still a high temperature on the sixth day after the eruption.

"Lying on the surface of this deposit, especially on the slopes directed towards the fissure, fragments of considerable size of various kinds of rocks were scattered about, and among these were masses evidently derived from the sinter of the terraces, and, from the manner in which these fragments appeared to occur in quantities where the finer dust had been blown from the surface, it is probable that the lower layer of the deposit will prove to be composed of coarser material than the upper. The boundary-line of this dazzling white deposit is very distinctly marked. It can be well seen where it passes over Kakaramea Mountain, dividing it, as it were, into two portions, one white and the other green. While traversing it we experienced a great downpour of rain, which formed the powdery material of the surface into little pellets; but it did not appear to be very absorbent, or to show any tendency to work up into an adhesive material. This is very different from what may be termed "the grey deposit" which is next to be mentioned, and which covers the country, from about two miles south of Wairoa, in a northerly direction towards the Bay of Plenty, as far as the Te Puke Settlement. This is the mud-forming deposit, and wherever it appears to have descended in a thoroughly pasty condition it coated the vegetation so heavily as to break limbs off lofty trees and to crush the smaller scrub flat simply by its weight. The sand, as already stated, appears to have fallen hot, so hot, indeed, as to set fire to the trees, the stumps of which were seen burning in many places; but there is nothing to lead us to suppose that this grey mud when it fell was even warm.

"It has been suggested by some that this moist deposit was mud thrown out from the bottom of Rotomahana Lake; but it is difficult to conceive how, in that case, it should have overleapt a strip of country four or five miles wide, where there is nothing but dry sand, before it reached Wairoa; and I think that a more likely source for its origin is to be found in the sudden condensation of the front edge of the great vapour-and-dust cloud when it suddenly met the violent cold south-west gale which averted it from Rotorua and directed it towards the sea-coast, where it spread over the sky and caused the darkness that was experienced at Tauranga and all over the country to the eastward. The great volume of this dust-cloud was directed towards the East Cape, dropping over the country in that direction a comparatively heavy deposit of brownish-black dust, so coarse as almost to be sand; while on its northern edge, as far east as Tauranga, the dust is of a light grey colour, and excessively fine in grain. A collection of all these different deposits has been obtained, and will be reported on as soon as the chemical analysis is complete. The impact of the moist deposit when it fell must have been very great, from the effects which it produced at Wairoa, where it appears to have attained its maximum thickness of about 12 inches in open level places free from any influence that would cause it to drift; on the flat spur above the bridge at the outlet of Rotokakahi its depth was found to be 9 inches, and in the Tikitapu Bush 4 inches; and from that point it gradually decreased towards the north. The action of rain upon this mud rapidly converts it into a semi-fluid condition, in which state it slides off the hill-slopes and fills the low grounds and watercourses; and where it has been thickly deposited it will thus be a constant source of danger for some time to come, but where only an inch or so in thickness it will, I believe, rapidly disappear, and, excepting that it may for a time deteriorate the pasture and destroy the existing vegetation, it will in the long run be an advantageous addition to the light pumice soils upon which it has been deposited, owing to its slightly absorbent properties. As for the light deposit of dust, which fell in a dry state, there is very little doubt that it will be all washed off into the soil with the first heavy rains that come. The distance to which this fine dust was carried was very great, exceeding at least 120 miles from the focus, in a direction between north and east; and the time it remained suspended in the atmosphere was at least eighty-four hours, as we passed through it in the *Hinemoa* when crossing the Bay of Plenty on the Saturday afternoon, as a peculiar yellowish fog, charged with pungent acid vapour and dust; and on the following afternoon we recognised the same fog-cloud still suspended in the atmosphere towards the north-east.

"V. *The Evolution of Steam.*—The enormous volume of steam rising from the site of Rotomahana Lake gives rise to a pillar of cloud that is visible in all directions over the country, having a diameter of about an eighth of a mile, and rising to a height of not less than 12,000 feet. Its effect is most impressive, especially in the morning and evening, when it is lighted up with gorgeous tints by the slanting rays of the sun when it is below the horizon, and all the surrounding landscape is in twilight. Although this steam-cloud receives rapid additions in its lower part from successive explosions, these do not generate any rapid movement through the mass of the cloud, so that, if viewed from a distance, it appears to be almost solid and immovable, except the changes that are gradually effected upon its lower portion by the movements of the atmosphere.

"VI. *The Propagation of the Earthquake Tremors.*—Earthquakes are the usual results of the violent concussions attendant upon violent outburst, and they afford the only clue which we can possibly have as to the depth below the surface of the earth at which the volcanic energy has been exerted. Thus, if the earthquakes are felt with only slightly-decreased violence to great distances from the focus of disturbance, it would indicate that the disturbance is a deep-seated one. On the other hand, if the earthquakes, although extremely violent close to the focus, are only felt at a moderate distance, the conclusion to be drawn is that the forces at work are only superficial. All reports agree that at the Wairoa, about four miles distant, which is the nearest point to the eruption from which any persons have survived, the shocks of earthquake during the first phase were violent and continuous; whereas at Rotorua, twelve miles distant, they were comparatively slight. The great earthquake at the commencement of the second phase appears to have been felt with considerable violence at Rotorua, and distinctly arrested attention for a distance of at least from sixty to seventy miles, but does not appear to have done any damage.

"During our visit the earthquake shocks in the vicinity of Rotomahana were still frequent and violent, but at Rotorua they were only experienced as gentle undulations; and I ascertained that they proceeded from the effects of the explosion from the Rotomahana fissure, and that the eruptions from the summit of Tarawera, which were clearly visible from Rotorua, did not produce the slightest apparent tremor at that distance. A few insignificant earthquake-rents were seen crossing the flats south of Kaitiriria, but only where there was a drop or unsupported bank.

"VII. *The Sounds.*—The sounds produced during the eruption must have been, from all accounts, appalling to those within a moderate distance. The crackling thunder produced by the electrical discharges, the terrific roaring of the high-pressure steam escaping through the volcanic vents, were combined with terrifying effects. Much has been said about noises heard at Auckland, Wanganui, and other places. From the times mentioned, these appear to have been due to the reverberating reports accompanying the Tarawera outbreaks. Some of these noises may have been propagated through the atmosphere, and reflected to the earth from the under surface of the stratiform cloud-sheets that were widely spread in various directions over the colony on that morning. Others, again, may have been propagated through the earth.

But I have been informed that at the whaling settlement of Tawaite, on the east entrance of Tory Channel, from six p.m. up to about eight p.m. on the evening of the 9th (the night preceding the eruption), loud booming reports were heard as through the earth. As these reports were previous to any symptom of the loud disturbances at Tarawera, this suggests that they may have resulted from a slight movement along the great fault-lines that traverse the North and South Islands in a north-easterly direction; and, in this case, the immediate cause of the Tarawera outburst may be found in a local fracture resulting from such movement.

"VIII. *Premonitory Symptoms.*—The only premonitory symptoms of the coming outburst which have been described were an oscillation in the level of Tarawera and Rotorua Lakes, and the occurrence of earthquakes for some months past in that district, where, as a rule, earthquakes are rarely felt. But neither of these are very characteristic incidents, nor would it be safe on future occasions to base any expectation of an eruption on such phenomena alone. The increased activity of the geysers and hot springs during the past season has also been advanced as having been a symptom of an approaching outbreak; but those who were most familiar with the district will agree that their variation was no greater than is usual under the influence of rapid changes of wind and atmospheric pressure. The reports of sympathetic outbreaks in other places along the line of volcanic energy from White Island to Ruapehu appear to be quite unfounded. The outburst has shown conclusively that the springs at Rotorua and Rotomahana are quite independent of each other, and of those at other places, thus confirming the observations made by Von Hochstetter long ago, that all the various points at which thermal springs occur are situated round the margins of lakes formed by subsidence of circular areas, and are not connected by an underground system of gravitational drainage.

"IX. *Conclusion.*—From the foregoing sketch of the character of the eruption I think there can be little question that it is a purely hydro-thermal phenomenon, but on a gigantic scale; that it is quite local and not of deep-seated origin, and that all danger is past for the present, so far as one can venture to form an opinion on such a subject. The extra activity of the *puias* which has been observed is no doubt owing to the heavy rains that, on the 9th, set in after the longest period of drought which has been experienced in that district for many years, and probably the frequent earthquakes which have of late agitated the ground have contributed to this activity by stirring up the sources of the water-supply, and facilitating the access of drainage-waters to the sources of the heat. But beyond what may be accounted for in this manner I believe there is no increased disturbance at Rotorua, Wairakei, Taupo, and other places. The quiescent condition of Tongariro and Ngaurahoe was plainly shown by the manner in which we observed it to be enveloped in snow. As a rule, on the scoria cone of Ngaurahoe, snow rarely lies, excepting in a few of the gullies, but melts almost as rapidly as it falls. On the morning of the 17th, however, the cone of Ngaurahoe was covered with a great mantle of snow; while the *puias* on Tongariro showed less than their usual amount of steam escaping. The only fresh activity which may be reasonably expected is that which I anticipate when sufficient rain has fallen to cause the overflow of Okaro Lake into the south end of the great fissure, as its former drainage outlet to the Rotomahana Lake appears to me to be completely filled up. If this should occur, and a fresh explosion takes place in consequence, it will be comparatively moderate in its effects, as, unlike Rotomahana, the soft, incoherent pumice deposits between the fissure and Okaro Lake are not sealed down by an enormous weight of siliceous sinter.

"For some time to come great variations must be expected in the activity of the newly-formed *puias* according to the manner in which changes occur in the atmospheric pressure; but, unless it can be shown that any local change in the barometer is experienced which is not shared by the surrounding district, the barometer affords no indication as to whether an eruption is or is not imminent. One of the most unfortunate results of the eruption, in addition to the disastrous loss of life and the destruction of the country, is the disturbance of the sense of security which has grown up amongst those residing at the Hot Springs; and I believe that many persons are so thoroughly shaken by the horrors experienced on the morning of the 10th that they will not recover their equanimity until they have been for some time resident away from the sounds, smells, and shocks that characterise the district. "JAMES HECTOR"

IN QUEST OF THE ORIGIN OF AN EPIDEMIC

IN our issue of the 8th ult. (vol. xxxiv. p. 213) we dwelt on certain general aspects of the reports lately laid before the President of the Local Government Board by the Medical Officer of the Department on milk-scarlatina, but these documents deserve more detailed consideration, for they show us our modern organisation for combating death and disease, by prevention, at its best. They show us, too, the men to whom the task of guarding public health is primarily committed at their best—patient, watchful, wary, tenacious of the thread of their investigation, eliminating this or that doubtful element, until finally they have tracked their quarry to its lair. In reading Mr. Power's report, we have been constantly reminded of that famous description of the contest between the man and the gun in Hugo's "Toilers of the Sea." Here the fight was man against disease, and the former has succeeded in his task. We shall endeavour in this article to show how Mr. Power, of the Local Government Board, succeeded in tracing, step by step, an epidemic of scarlatina to its source.

On December 18, 1885, Mr. Winter Blyth, the Medical Officer of Health of St. Marylebone, reported to the Board an extensive outbreak of scarlatina in his district. This he believed to be associated with the distribution of milk from a certain retailer in South Marylebone, who obtained his supplies from two farms, but the occurrence of the scarlatina appeared to be coincident with the milk-distribution from a certain farm at Hendon. Mr. Blyth had himself visited this farm, and, with the assistance of Dr. Cameron, the Hendon Medical Officer of Health, had carefully examined it, but was quite unable to discover in its sanitary circumstances or in the health of those employed about it any sort of clue to the cause of the infection of the milk. Accordingly he went with his story to the Local Government Board. It will be seen that Mr. Blyth had done his work exceedingly well: in one of the most crowded districts of London he had succeeded in tracing the scarlatina to a farm at Hendon; that is, he had made out a strong *primâ facie* reason for suspecting this farm; he had put a clue into Mr. Power's hands which he had not been able to follow any further himself. The first question for Mr. Power to answer was whether the Hendon farm was at fault or not. When this was answered it would be time enough to pursue the inquiry more minutely: it would be loss of time to try to dig out the fox unless it was first ascertained that he was in that particular earth. With this object, then, Mr. Power traced the milk from the Hendon farm to other milk-retailers in St. John's Wood, St. Pancras, Hampstead, and Hendon itself. From each of these, except St. John's Wood, the same story came. Until the end of November or beginning of December the district had for some months been exceptionally free from scarlatina, but about

this date the disease had suddenly and notably increased, a large proportion of the recorded cases having occurred amongst the customers of milk-retailers dealing in the particular Hendon milk. These facts strengthened the case against the Hendon farm, but did not by any means establish it, inasmuch as the retailers in question obtained their supplies from other farms as well, and although in two cases these were situated in widely different counties, yet the case against Hendon was still in the condition of not proven, more especially as the St. John's Wood customers of that farm were certainly wholly free from scarlatina. Simultaneously with this investigation, another was being pursued at the incriminated dairy itself. But nothing was revealed here to show how the disease could be propagated from it as a centre. There was no scarlatina, nor any illness at all like scarlatina, amongst the persons employed about the farm, or their families and neighbours, at any such time or in any such way as to influence the farm or its produce. This, then, was the state of affairs on December 23, or less than a week after Mr. Blyth's report: there was a strong presumption against the Hendon farm, but outside human agencies had to be set aside as not having been operative. A thorough inspection of the farm itself was at once undertaken. Now it happened that the farmer in question, as well as one of the dealers who purchased from him, was particularly careful in all sanitary matters respecting his dairy. Every precaution had been taken by both to secure the farm and milk against any known sanitary fault or misadventure, and thus the inquiry advanced another stage. If the Hendon farm had caused the scarlatina, it did not do so in any commonly accepted way, such as through unwholesome conditions of water or drainage, or careless handling of milk or milk-utensils, by persons carrying scarlatina infection. This threw Mr. Power back on the theory of something in the cows themselves which caused the scarlatina to be distributed with their milk, and this formed his working hypothesis thenceforth. To discover this "something," and to understand its nature, it was necessary to ascertain in detail every parallel between the doings at the dairy farm and the observed scarlatina.

Here, then, we enter on the second and by far the most difficult stage of the investigation. The various districts supplied from Hendon were taken one by one; the quantities of milk obtained from Hendon by the dealers there, and by the same dealers from other sources, were ascertained; the dates of the notable incidence of the disease among the customers, and the degree of incidence at one period and another, were carefully observed, and compared, with the following results:—(1) The disease commenced at one and the same time in the four districts supplied from Hendon, viz. South Marylebone, Hampstead, St. Pancras, and Hendon. (2) In South Marylebone the disease increased day by day with increasing force up to the date of the inquiry. (3) In Hampstead and St. Pancras there was a cessation of ten days after the first attack, and then a larger number of persons were taken ill, the attacks continuing up to the date of the inquiry. (4) In St. John's Wood there was no scarlatina whatever down to the date of the inquiry, although the dealer there got five-sixths of his milk from Hendon. Were there any conditions in the farm operations parallel to these special phenomena? And first, was there any new condition pertaining to the cows coincident with the milk producing scarlatina at the end of November in four districts, continuously in South Marylebone, and after a break in the other three, while this condition was absent in the case of the cows supplying the St. John's Wood dealer? A tedious inquiry into such circumstances as the food, calving, health, arrival and departure of cows proved barren of result; nothing could be heard of for some time that was new or changed. But at last it appeared that on November 15 three newly-calved cows, purchased in Derbyshire, had come on the farm, and four from Oxfordshire on December 4. The practice of the farm was to isolate or quarantine new arrivals for examination for a week or ten days, and then to admit them into the stalls with the others. The cows on the farm at this period numbered 90 or 100, distributed in unequal numbers in three sheds, called the large, middle, and small sheds. The supply of the milk from the large shed went to South Marylebone only; that from the middle shed partly to South Marylebone, partly to Hampstead and St. Pancras; and that of the small shed to the two latter places and to St. John's Wood. So far we have this coincidence between the doings at the farm and the incidence of the disease—that the latter broke out after the time that the milk of the Derbyshire cows was added to the general stock, in three districts supplied from the farm; and that St. John's Wood, which did not receive any milk from the new arrivals, was free from scarlatina.

We have now reached what may be called the third stage of the case. In the first, what Mr. Power calls a "notable," and what lawyers perhaps would call a "violent," presumption had been made out against the Hendon dairy; in the second, a weaker presumption had been established against the Derbyshire cows which had been added on November 15, and whose milk began to be distributed to the three affected districts, and not to St. John's Wood, a few days later. But then, the facts of a continuous and increasing attack in South Marylebone, and the intermission of about ten days in St. Pancras and Hampstead, had to be accounted for, if the case was to be made out conclusively against the incriminated dairy. To deal with these, Mr. Power reversed the process hitherto pursued, which was that of pure induction from observed facts. He now employed the *a priori* process, and argued thus:—Taking the fact of uninterrupted progress of the disease in South Marylebone, and of the lull of ten days in the other two, if the dairy at Hendon be the cause of the outbreak, and if, as is most probable, the different results produced by the milk from the same cows was due to a difference in the relation of the cows themselves within the business of the farm, then we should find at the latter—(1) a change in the manner of distributing the milk of the Derbyshire cows, and this probably consisting in placing them, or one of them, in the "large shed," from which South Marylebone was supplied; (2) about the second week in December (the date of the recrudescence of the disease in St. Pancras and Hampstead), some of the Derbyshire or of the Oxfordshire cows, or some other cows which had been in close relation with them, were probably transferred to the "middle shed," from which these two districts were, it will be remembered, supplied; (3) as St. John's Wood, which was supplied from the "small shed," was free from scarlatina, it should be found that none of the new cows, or any other cow in close relation with them, had been placed there. Now, were any arrangements at the farm found corresponding with any or all of these *a priori* conclusions or probabilities? What was found on investigation was this: (1) The Derbyshire cows had been transferred towards the end of November into the "large shed" (the source of the South Marylebone supply), and remained here at the date of the inquiry; (2) the four Oxfordshire cows were transferred about December 11, two into the "large shed," and two into the "middle shed" (St. Pancras and Hampstead supply); (3) at no time had either the Derbyshire or Oxfordshire cows been transferred to the "small shed" (St. John's Wood). Here, then, both by positive and negative evidence, the presence of scarlatina in certain London districts was associated, first, with a particular dairy, and secondly, by a series of parallel events, with certain cows within that dairy. Mr. Power, having reached this point, felt justified in assuming, until anything to the contrary should appear, the presence

of something in these cows competent to produce scarlatina in persons consuming their milk, and the inquiry was narrowed to determining what this was. All comparison with former experiences was for the present left out of consideration, the investigation proceeding strictly on the circumstantial evidence obtained and obtainable. A consideration of all that had gone before, and the absence of any alternative, led to the provisional adoption at this point of a theory of disease in the cows, and the probability was that this was an infectious disease, communicable from cow to cow, a disease, moreover, the existence of which was compatible with the animal affected feeding well, and milking abundantly.

The discovery of vesicles and ulcers on the teats and udders of cows in the large shed soon followed; the first to show the disease was one of the Derbyshire cows, the second one from Oxfordshire. After this the matter passed into Dr. Klein's hands; but with his report we have nothing to do here. A painful incident soon gave Mr. Power ample corroboration of the result which he had reached. The Marylebone dealer returned on the farmer's hands, on December 15, all his milk from the larger shed, and this was destroyed by pouring it into a pit dug on his land. The news of the destruction of milk spread among some of the poor people of Hendon, and some of them succeeded by the favour of friends amongst the cowmen in obtaining some of it on December 16. By the 20th scarlatina made its appearance amongst half-a-dozen of the families thus supplied. Conversely in South Marylebone about Christmas, when these Hendon families were falling ill, the disease ceased almost suddenly, and there were no fresh attacks, except such as were referable to infection from previous sufferers.

A thorough examination of all the cows showed that the disease had spread to every one of the three sheds, and the farmer was accordingly advised to seek out every cow then or afterwards affected with sore teats or udder, or any other ailment, to isolate her and keep all her milk out of the business, and prevent cowmen employed about the sound cows from attending the infected ones. These precautions were taken from January 1, and were barely in time to prevent an alarming increase of scarlatina in all the districts served from Hendon, including St. John's Wood, where the appearance of scarlatina corresponded to a nicety with the appearance of the cow-disease in the animals in the small shed. The milk from the Hendon farm was ultimately given up by all the dealers concerned, with the result that scarlatina has disappeared from amongst the customers of the dealers here referred to in Marylebone, St. Pancras, Hampstead, and St. John's Wood. The work of demonstrating the nature of the cow-disease, and its connection with human scarlatina was not Mr. Power's, and from him the matter passed on to Dr. Klein. The former had succeeded in gathering up and connecting the scattered links of a chain of presumptive evidence against certain cows so strong as to be unassailable; and he had done this by the exercise of patience, sagacity, and acuteness which would have done credit to a great criminal lawyer weaving the web of circumstantial evidence around an unusually cunning forger or murderer.

THE ORIGIN OF VARIETIES

THE publication in the three last numbers of NATURE, by Mr. Romanes, of very important papers,[1] induces me to send the following lines as a contribution to the discussion upon them that is sure to ensue. He ascribes the origin of varieties to peculiarities in the reproductive system of certain individuals, which render them more or less sterile to other members of the common stock, while they remain fertile among themselves. I also have a theory which, while it differs much from that of Mr. Romanes, runs on curiously parallel lines to it, and was prompted by the same keen sense of an inadequacy in the theory of Natural Selection to account for the origin of varieties. I should not have published my views until they had been far more matured than they are had not the present occasion arisen.

It has long seemed to me that the primary characteristic of a variety resides in the fact that the individuals who compose it do not, as a rule, *care to mate* with those who are outside their pale, but form through their own sexual inclinations a caste by themselves. Consequently that each incipient variety is probably rounded off from among the parent stock by means of *peculiarities of sexual instinct*, which prompt what anthropologists call endogamy (or marriage within the tribe or caste), and which check exogamy (or marriage outside of it). If a variety should arise in the way supposed by Mr. Romanes, merely because its members were more or less infertile with others sprung from the same stock, we should find numerous cases in which members of the variety consorted with outsiders. These unions might be sterile, but they would occur all the same, supposing of course the period of mating to have remained unchanged. Again, we should find many hybrids in the wild state, between varieties that were capable of producing them when mated artificially. But we hardly ever observe pairings between animals of different varieties when living at large in the same or contiguous districts, and we hardly ever meet with hybrids that testify to the existence of unobserved pairings. Therefore it seems to me that the hypothesis of Mr. Romanes would in these cases fail, while that which I have submitted would stand.

The same line of argument applies to plants, if we substitute the selective appetites of the insects which carry the pollen, for the selective sexual instincts of animals. Both of these, it will be remembered, are mainly associated with the senses of smell and sight. If insects visited promiscuously the flowers of a variety and those of the parent stock, then—supposing the organs of reproduction and the period of flowering to be alike in both, and that hybrids between them could be produced by artificial cross-fertilisation—we should expect to find hybrids in abundance whenever members of the variety and those of the original stock occupied the same or closely contiguous districts. It is hard to account for our not doing so, except on the supposition that insects feel a repugnance to visiting the plants interchangeably.

No theme is more trite than that of the sexual instinct. It forms the main topic of each of the many hundred (I believe about 800) novels annually published in England alone, and of most of the still more numerous poems, yet one of its main peculiarities has never, so far as I know, been clearly set forth. It is the relation that exists between different degrees of unlikeness and different degrees of sexual attractiveness. A male is little attracted by a female who closely resembles him. The attraction is rapidly increased as the difference in any given respect between the male and female increases, but only up to a certain point. When this is passed, the attraction again wanes, until the zero of indifference is reached. When the diversity is still greater, the attractiveness becomes negative and passes into repugnance, such as most fair-complexioned men appear to feel towards negresses, and *vice versâ*. I have endeavoured to measure the amount of difference that gives rise to the maximum of attractiveness between men and women, both as regards eye-colour and stature, chiefly using the data contained in my collection of "Family Records," and have succeeded in doing so roughly and provisionally. To determine it thoroughly, and to lay down a curve of attractiveness in which the abscissæ shall be proportional to the amounts of difference, and the ordinates to the strength of attraction, would require fresh and special data that have

[1] I write from abroad, and have not yet seen the original memoir published by the Linnean Society.

yet to be collected and discussed, and about which I will not now speak. Suffice it to say that such inquiries as I have made confirm, so far as they go, the reasonable expectation that some more or less regular curve will be found to exist in respect to any given quality or group of qualities. Each individual would possess his own characteristic curve, but the average of the tastes of many individuals would, as all statistical experience justifies us in believing, afford fairly constant data. These would enable us to argue out the hypothesis I have submitted, with mathematical precision; at all events, with much more closeness of reasoning than is now possible. But this much may even now be averred: (1) That the existence of a law of sexual selection such as I have described, is probable; (2) if it exists, it would have a powerful influence in rounding off any incipient variety that differed notably in any one particular or in any group of particulars from the parent stock; (3) it would be favourable to the vigour of the variety, after it was once fairly started, by checking too close interbreeding.

It must be borne in mind that differences overlooked by ourselves, who are singularly deficient in the sense of smell, and who are hardly able to distinguish without scrutiny even the sexes of some animals, may seem very considerable to the animals themselves. Also that the only differences that we are able to recognise between two varieties may connote a host of unseen differences, whose aggregate would amply suffice to erect a barrier of sexual indifference or even repugnance between their members.

FRANCIS GALTON

August 23

NOTES

THE Local Committee of the Birmingham meeting of the British Association has issued a descriptive programme of the excursions which have been arranged for Saturday, September 4, and Thursday, September 9. The programme covers 120 pages, and has been compiled by several specialists with the greatest care. There are twenty-seven excursions in all, besides a geological excursion to the Lower Palæozoic district of Shropshire. This excursion will last six days, from September 9 to September 15. Prof. Lapworth will take the leadership.

THE French Association for the Advancement of Science has concluded its annual meeting at Nancy, after having resolved that the 1888 session will be held in Oran, Algeria; Col. Laussedat has been elected President for that meeting. The 1887 session will be held in Toulouse, as decided at the last meeting.

AT the Buffalo meeting of the American Association it was proposed to devote especial attention to the study and discussion of the interesting phenomena of the Niagara Falls and the gorge below. On Friday, August 20, one or more preliminary papers of an expository and suggestive nature were to be given, intended to prepare the way for a short field-study of the Falls and the gorge, which occupied Saturday. Monday forenoon would be devoted to the discussion of the gorge and the problems to which it gives rise. A new survey of the Falls has been arranged for, so that a considerable addition to the data for the computation of the rate of recession will be at command, and it is expected that new observations in other important lines bearing upon the chronology of the gorge will be presented, and will throw fresh light upon the history of the formation and recession of the Falls, and upon the utility or untrustworthiness of the gorge as a geological measure of time.

WE learn that the Lick Trustees—after a most thorough discussion of the various plans and specifications submitted for the mounting of the 36-inch refractor of the Lick Observatory and for the steel dome to cover the same, and with a special consideration of the element of time, which circumstances now make one of vital interest to the work—have let the contract for the former to Warner and Swasey of Cleveland, Ohio, for 42,000 dols., and the contract for the latter to the Union Iron-Works of San Francisco for 56,850 dols. The Trustees acknowledge the very prompt and courteous manner in which Mr. Grubb has responded to their invitation, and the very great disadvantage to which he has been put by the remote situation of his works from California, &c. The President of the Trustees has stated that he believes that Mr. Grubb's idea of an elevating floor in principle offers the best solution yet submitted of the very difficult problem of a convenient chair for the observer with so large a telescope. The method of elevating the floor will have to be adapted to the peculiar circumstances of the site of the Lick Observatory, and the means to be commanded there with its very limited water-supply. This subject is now being carefully studied, and so far the only apparent obstacle to the adoption of Mr. Grubb's plan is the question of cost.

WE have to record the death, at Tomsk, of Alexander Krapotkin, on August 6, at the age of forty-five years. M. Krapotkin had done some good work for science in Russia. He had translated into Russian Mr. Herbert Spencer's "Principles of Biology," and Clerk-Maxwell's "Theory of Heat," and for several years contributed to Russian periodicals reviews of the progress of physical astronomy, much valued by Russian astronomers. In 1874 M. Krapotkin was exiled to Minusinsk in East Siberia, and there he helped Dr. Martianoff to organise a local museum; and for several years carried on meteorological observations, which were printed by the Kazan Society of Naturalists. His most important work, however, was a critical investigation of all our present knowledge of the stellar systems and constitution of stellar groups. Every known source in every European language was ransacked for data, though the difficulties he encountered in his peculiar position prevented him from bringing his work down to a later date than 1879. He hoped to complete the work, and publish it, after his expected liberation in September. His untimely death has put an end to this hope.

WE have received the third number of the *Journal* of a Society recently founded in Bombay, called the Natural History Society of Bombay, which, though it is young, appears to have abundant vitality. There are already several learned societies in India and Ceylon, all of which appear to be very successful; but the field is so vast and varied, and the number of men, servants of the Crown and others, capable of doing good work is so great, that it is impossible to have too many of these associations, and accordingly we welcome the new Society, and are glad to notice the energy it displays. In the number of the *Journal* before us, Capt. Becher describes the life (mainly the bird-life) of a Sind lake, Manchar, near the Indus; "A member of the Society" similarly compiles some notes on animal life in the rivers of British Deccan and Kandesh. Mr. Sterndale, one of the editors, has a paper, with illustrations, on abnormalities in the horns of ruminants, in which he expresses the opinion that there is neither persistence nor transmission in the abnormalities of antlered deer, but that they must be persistent in the case of hollow-horned ruminants, and that in the latter case the adage is true: "As the twig is bent, so is the tree inclined." Mr. Aitken, the second editor, publishes a list of the Bombay butterflies in the Society's collection, with notes. The collection appears to be far from complete in any direction. Dr. Kirtikar describes a new species of Alga (*Conferva thermalis Birdwoodii*), discovered among the hot-water Algæ in the hot springs of Vajrabai. There are, in conclusion, various zoological and botanical notes, and a list of presentations to the Society, which we notice in order to mention that they appear to be of great number and variety. One present is a collection of 105

birds. The new Society evidently has many friends and supporters.

AMONGST the great number of publications which are received from time to time from the Smithsonian Institution, two which have lately been issued help better perhaps than anything else to show the magnitude of the work of the Institution as a disseminator of scientific knowledge—a work, moreover, the sphere of which is limited only by the civilised world. The first of these is the list of institutions in the United States receiving the Smithsonian publications. The latter "are so distributed as to be accessible to the greatest number of readers," and the rules for distribution are accordingly of a very elastic kind, giving abundant discretion to the authorities. The publications are divided into three classes: (1) the reports; (2) the miscellaneous collections; (2) the contributions to knowledge. Of these, one, two, or all classes are distributed according to the demands of the neighbourhood to which they are sent, and all that is required in return is that they be "duly acknowledged, be carefully preserved, be accessible to any person who may wish to consult them, and be returned to the Smithsonian Institution in case the establishment at any time ceases to exist." The list of institutions in the United States receiving the publications under these conditions fills a pamphlet of about seventy pages, and numbers nearly 2000. They include various classes of schools and colleges, literary and scientific institutes, learned societies, public libraries, hospitals, &c., in wonderful variety. In looking through the list it is impossible not to recollect the trouble with which a few of our own public institutions succeeded last year in getting some of the Parliamentary papers published by the Government.

THE second publication to which we have alluded is the Smithsonian list of foreign correspondents, in other words, of institutions outside the United States to which the Institute's publications are sent. These reach the enormous number of 7969, every country on the globe with any pretence to civilisation being represented. It thus appears that an ordinary Smithsonian Report has a free circulation of about 10,000, and is spread all over the globe, from Pekin to Valparaiso, from Iceland to New Zealand. The exchange department of the Smithsonian is certainly not the least marvellous part of a marvellous institution.

ACCORDING to the latest consular report from Newchwang, in Manchuria, Seoul, the capital of Corea, is now in telegraphic communication with Pekin, and so with the outer world. The line runs through Moukden. Six years ago no European was allowed to visit Corea, and those who ventured to disregard Corean seclusion generally paid for their temerity with their lives: to-day a merchant in London might telegraph direct to the capital of the Hermit Kingdom.

A SHOCK of earthquake was experienced on Friday evening at Kilsyth, a mining town situated in Stirlingshire, about thirteen miles from Glasgow. About 9 o'clock a sharp rumbling noise of a few moments' duration was heard over the greater part of the town. Much vibration was noticed in many houses at the same time. People ran immediately into the streets, not knowing what had occurred, and many rushed off to the Craig Ends and Haugh pits, situated to the east and west of the town, thinking that one or the other must have been the scene of a great disaster. The shock was most distinctly felt in the north-east portion of the burgh. The weather at the time was close and dull.

ANOTHER slight shock of earthquake was felt at Malta at 8.30 a.m. on August 19. The captain of a steamer which arrived there on the 18th, officially reports that at about 9 o'clock on the evening of the 17th inst. he observed something like a blaze of fire coming out of the water. It was about 30 feet wide and rose to 100 feet above the water, and disappeared at once. The position of the steamer at the time was about 200 miles eastward of Malta. The blaze was observed at the head of the ship, and those on board were certain that it was not lightning.

A CURIOUS result of the volcanic eruption in New Zealand (according to the *Colonies and India*) is alleged to have been found in the sudden breaking up of the drought in Australia. It is said that the great Java earthquake of 1883 was the immediate forerunner of a long spell of dry weather in Queensland in that year, and that a welcome fall of rain in the same colony followed immediately upon the eruption of Mount Tarawera.

MR. F. W. PUTNAM's last report of the explorations which he is conducting with Dr. Metz in Ohio for the Peabody Museum, deals with what is called the Marriott Mound, No. 1, forming part of the Turner group in the Little Miami Valley. The report describes with great minuteness the various objects found in this mound, of which numerous illustrations are given. The find was a rich one. The mound, though it had been ploughed over, was 2 feet high and 60 feet in diameter at the time of the examination. In the centre was found a mass of burnt clay in the shape of a basin, 2 feet in diameter, containing ashes, charcoal, burnt bones, pottery beads, and various shells used as ornaments. About 600 fragments of pottery, from 2000 to 3000 broken and split pieces of bones of animals (chiefly the deer and bear), shells of river clams, several objects in bone and stone, and some human remains, were amongst the objects found in the mound. Of the latter the principal were a perforated skull, various bones belonging to a different skeleton, a third skeleton, partly covered by a large hammered copper plate, and a fourth, which was apparently that of a woman, with numerous personal ornaments near it. Mr. Putnam's report is confined to a bare description of all these and other objects found, and of their precise situations in the mound with regard to the basin in the centre and to each other.

AT the annual meeting of the Royal Society of Queensland, held at Brisbane on July 2, the President, Mr. L. A. Bernays, delivered an address in which he gave a brief *résumé* of the work of the Society during the past year, its meetings, and the publication of the papers read on these occasions, the endeavour to assist in the exploration of New Guinea by organising a fund for the benefit of the Forbes Expedition; the efforts to encourage special scientific pursuits amongst the members by the admission of Sections into its constitution. Finally, having dwelt on the importance of the conduct by the State of systematic instruction with the immediate object of fostering numerous industries which the marvellous range of soil and climate of the colony is capable of calling into existence, occasion was found to dwell on the value of technical and industrial botany, and the importance of its recognition in the plan and management of the colonial botanical gardens, and in the selection generally of objects publicly displayed for educational purposes. With regard to the Forbes Exploration Fund referred to by the President of the Queensland Royal Society, in December last Mr. H. Tryon suggested to the Council of the Society that such a fund should be opened in Queensland. This was done, and at the time it was closed 94*l*. was raised. Subsequently a further appeal was received on behalf of Mr. Forbes, whose operations had been suspended. This led to the fund being reopened, with the result of additional subscriptions being received, raising the total to 145*l*. 10*s*. For a Society which is quite young, and the total income of which is but little over 100*l*. per annum, this is a considerable donation to Mr. Forbes's work, even though Queensland has a special interest in New Guinea.

THE additions to the Zoological Society's Gardens during the past week include an Egyptian Gazelle (*Gazella dorcas*) from Egypt, presented by Capt. Robbins; two Red-under-winged Doves (*Leptopila rufaxilla*) from Guiana, presented by Mr. S. Wells; a Barn Owl (*Strix flammea*), British, presented by Sir Henry Tyler; two Great Eagle Owls (*Bubo maximus*), bred in Shropshire, presented by Viscount Hill; three Yellow-headed Conures (*Conurus jendaya*) from South-East Brazil, presented by Mr. C. Rudge; a Raven (*Corvus corax*), British, presented by Mrs. Tatham; a Martinique Gallinule (*Porphyrio martinicus*) from South America, presented by Mr. J. M. Booker; two Common Boas (*Boa constrictor*) from South America, presented by Mr. T. H. Church; a Common Viper (*Vipera berus*), British, presented by Mr. R. B. Spalding; four Ruscon's Newts (*Molge rusconi*) from Sardinia, presented by Prof. H. H. Giglioli, C.M.Z.S.; two Black-eared Marmosets (*Hapale penicillata*), a Feline Dourocouli (*Nyctipithecus vociferans*), two Yarrell's Curassows (*Crax carunculata*), two Magpie Tanagers (*Cissopis leveriana*), two Ariel Toucans (*Ramphastos ariel*), two Laughing Gulls (*Larus atricilla*), a White-faced Tree-Duck (*Dendrocygna viduata*) from South-East Brazil, purchased; three Aldrovandis Skinks (*Plestiodon auratus*) from North-West Africa, two Common Slow-worms (*Anguis fragilis*), British, received in exchange; six Ribbon Snakes (*Tropidonotus saurita*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *AUGUST* 29—*SEPTEMBER* 4

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on August 29

Sun rises, 5h. 9m.; souths, 12h. 0m. 46·9s.; sets, 18h. 52m.; decl. on meridian, 9° 18′ N.: Sidereal Time at Sunset, 17h. 24m.

Moon (New) rises, 4h. 51m.; souths, 11h. 58m.; sets, 18h. 52m.; decl. on meridian, 9° 21′ N.

Planet	Rises	Souths	Sets	Decl. on meridian

August 29.—Total eclipse of Sun: not visible in Europe. The central line crosses the West Indies, the Atlantic, and Southern Africa. The members of the British Expedition are prepared to observe the eclipse at Grenada, one of the Windward Isles, where the eclipse will occur soon after sunrise, having a duration of totality of about 4 minutes. In mid-Atlantic the duration will be 6 minutes. In Africa the eclipse occurs near to sunset, with a duration of totality of about 4 minutes.

GEOGRAPHICAL NOTES

IN a lecture delivered at Cooktown (published in the *Daily Observer* of Brisbane), Mr. H. O. Forbes described his work in New Guinea during the six months he remained there. He set up his winter camp at Sogere, three days' march from the coast, though only 25 miles in a straight line, on the slope of a steep mountain. His work here was varied and important. The meteorological station which was erected was placed under the charge of Mr. Hennessy, and the observations were continued down to the end of his stay. These consisted of records of the mercurial barometer, maximum and minimum, dry- and wet-bulb thermometers, and rainfall, and were recorded without interruption six times in every twenty-four hours. The mass of observations thus accumulated will take a considerable time to tabulate, especially those referring to the atmospheric humidity. Then there was the collecting of zoological and botanical specimens. A large portion of the herbarium consists of giant trees of the forest. It contains about one thousand specimens, one set having been sent to Baron von Müller to Melbourne. A great part of Mr. Forbes's own time was devoted to the survey and delineation of the geographical features of the country. He obtained angles from about fifty different stations and established a base of several miles in length, on which he had hoped to found the triangulation of the country between Sogere and Owen Stanley, and the north-east coast. He also paid a visit to the latter place, and there, as elsewhere, with a little management, found the natives extremely friendly and well-disposed. When Mr. Forbes found his funds failing, he determined, with Mr. Chalmers, on making a dash for Mount Owen Stanley, but the natives who were to have aided him fled in the night, apparently on account of the terrors inspired by the journey. He only got as far as Kaukari, a village two days' journey beyond Sogere. He says that no words can give a true idea of the break-neck, shattered, disrupted condition of the country between Sogere and the central ridges. Beyond the natural obstacles, however (and they appear to be very great), there appears no reason why British New Guinea should not be thoroughly explored, provided the natives are treated with conciliation and tact.

THE Hon. Duncan Gillies, Premier of Victoria, has received a deputation, consisting of members of various learned societies, who urged the expediency of Antarctic exploration. The deputation represented that whale-fishing would make the enterprise remunerative, but at the same time asked the Victorian Government to give encouragement to the project. The Premier, in reply, said that the Government would be willing to grant a subsidy to aid scientific discovery, and that he would ask the other colonies to do the same. In the meantime he would instruct the Agent-General in London to inquire whether steam-whalers would be disposed to embark in the enterprise, and what subsidy would be required.

THE annual meeting of the Association of Swiss Geographical Societies took place at Geneva, at the same time as that of the Society of Natural Sciences. Prof. Chaix was President. Geographical Societies exist now in Geneva, Berne, St. Gall, Aarau, and Neuchatel, and others are about to be established in Zurich, Basle, and Lausanne. Those in existence count altogether more

than a thousand members. The paper which attracted most attention was one by Prof. Forel, on Lake Leman. He gave an historic sketch of the examination of the bed of the lake from Delabèche in 1819 down to the present day, from which it appeared that the knowledge of the central portion is very incomplete, while the rest of the lake is now well known. It is clear that there are two parts in the lake of wholly different character—one small and shallow, the other large, deep, and Alpine in its character. These two are separated by the Yvoise bank or bar, which is really a glacial moraine, as shown by the flints dredged up. These fragments of rock, found sometimes at a depth of 61 metres, are covered with moss of a beautiful green—a fact which appears to demand a reconsideration of the theory that light will not penetrate to more than 25 metres. A discovery in connection with the lake which M. Forel regards as a most interesting one in physical geography is that of a sub-lacustrine ravine through which the Rhone flows. Prof. Forel's long and laborious study of the lake entitled him, the President said, to the title "Prophet of Leman." Dr. Dufresne described the orohydrography of Brazil, and M. Brun recounted his adventures on the Gran Chaco. The Association discussed at some length various questions connected with the teaching of geography, especially the compilation by the allied societies of a manual of geography, and the establishment of geographical museums.

THE current number of the *Verhandlungen* of the Berlin Geographical Society (Bd. xiii. No. 6) contains two papers on the Congo region: one by Dr. Büttner on his journey from San Salvador to the Quango, and thence to Stanley Pool; the other by Lieut. Kund, who, with Lieut. Tappenbeck, was sent out by the German African Society in 1884. Their task was to explore the southern tributaries of the Congo, and to study their navigable qualities between Koango and Kassai. The length of the journey was, in all, 800 German miles, of which 340 was by water, and 460 by land. They succeeded in finding, between Koango and Kassai, three navigable rivers, the Wambu, Saie, and Kiulu; and they regard Lukenje, with its people, as practically a new discovery in the Congo basin. Dr. Joest writes on Minahassa, a peninsula in the north-east Celebes.

THE *Zeitschrift* (Bd. xxi. Heft 3) contains less matter of specially geographical interest than usual. A short paper, with an excellent map, discusses the improvements, which appear to have been great, made in recent years in roads and other means of communication in Asiatic Turkey. The greater part of the number is occupied with an exhaustive examination, by Herr Jung, of the census of India for 1881. The only real geographical paper is a summary of the report presented to the Brazilian Government on the surveys made for the purpose of the frontier between that empire and Venezuela.

THE last number of the *Izvestia* of the Russian Geographical Society (1886, ii.) is of great interest. It contains a beautiful map of the upper course of the Amu-daria, on the scale of 20 miles to an inch, including the space between the 36th and 41st degrees of latitude, and the 66th and 76th degrees of longitude. The whole of the Pamir appears on this map according to the recent surveys and barometric levellings of the Pamir Expedition, while a number of other surveys, including those of M. Kosyakoff (who accompanied Dr. Regel), the astronomical determinations of MM. Scharnhorst, Bansdorf, Schwartz, Skassi, Putyata, and Mr. Forsyth, as also the sketch map "of M. S. in and around Badakshan," have been taken into account. The same issue contains a very interesting paper by M. Grum-Grzymailo on the Pamir region; a paper, by M. Makaroff, on the double currents in straits, and especially in the Bosphorus (being a summing up of papers on this subject published in the *Memoirs* of the St. Petersburg Academy of Science); a most interesting account of the earthquakes at Tokmak in 1885; and, finally, the minutes of the proceedings of the Society brought up to a recent date, that is, embodying the sittings of the Society and its Sections as far as April last.

THE last issue (Nos. 5 and 6, 1885) of the *Journal* of the North China branch of the Royal Asiatic Society has a paper by Mr. Phillips on the seaports of India and Ceylon, described by Chinese voyagers of the fifteenth century, with an account of Chinese navigation. It is illustrated by a very curious old chart said to have been used by Chinese sailors who visited these distant places. In the present paper the route from Sumatra by the Nicobars to Ceylon is described; at a future time the writer will continue the maps to Arabia and Persia. The method of navigation by star charts, one of which is given, is very interesting. The whole paper shows that the Chinese visited these seas long before European navigators found their way there.

THE INSTITUTION OF MECHANICAL ENGINEEERS

THE summer meeting of this Institution for the reading and discussion of papers was held on the mornings of the 17th and 18th inst., at the Theatre of the Institution of Civil Engineers. On the afternoons of these days, and on the 19th and 20th, various works in and about London were visited. The Institution was entertained three years ago by the Belgian Engineers at Liége, and on this occasion Belgian Engineers have enjoyed the hospitality of the London members of the Institution.

The proceedings commenced with a few introductory remarks and a welcome by the President, Mr. Jeremiah Head, after which he read an address, taking as the text of his discourse the "Depression of Trade," to which Dr. Percy referred at the meeting of the Iron and Steel Institute in Glasgow last autumn, attributing it to over-production.

Mr. Head drew attention to the circumstance that mechanical engineers had done their utmost to make possible what had actually occurred, illustrating his remarks by recalling to the minds of the members some of their recent visits to works in various parts of England, where "the advantages of adhesion to a few types, and to but a few sizes of each type, of working to gauges throughout, of the piece-work system, of making for stock as regards all details, and taking from stock when erecting so as to avoid delays, impressed themselves strongly upon the members, who realised what rapid strides had been made in the direction of increased production at diminished cost." He instanced a steam-navvy, which was capable of doing the work of 80 to 120 human navvies, thus turning them into the ranks of the unemployed, and the flooding of our markets with American and Swiss watches, which, according to the evidence of a Liverpool watchmaker, was killing the British industry. The probable causes of these unfortunate circumstances were "diffusion instead of concentration, and adherence to old habits instead of quick appreciation of new and better ones."

Passing from the subject of the aid rendered by mechanical improvements towards over-production, the speaker referred to various commodities we send abroad as affecting our trade. "Some of these commodities may, in their production and sale, beneficially affect us now, and may also bring other benefits in the future; others may be profitable for the time being, but may tend to destroy future trade."

The address was listened to with interest and attention by the members, the meeting being one of the largest that has taken place in the metropolis for some time.

Two papers only were read on this occasion, the one by Mr. Borodin, of Kieff, and the other by Mr. Sandiford, of Lahore, both being on the working of compound locomotives, Mr. Borodin's paper also having reference to steam-jacketing. Mr. Borodin employed Mr. G. A. Hirn's system of investigation, with some modifications necessary to adapt it to locomotives working without condensation. Tests were first made in the locomotive testing-shop, where there was no dynamometer, and as only 90 per cent. could be utilised, high grades of expansion and comparatively low pressures had to be employed. The arrangements made were very complete; pressure-gauges and counters were observed, and indicator-diagrams taken at frequent intervals, the readings of which were tabulated. The results of each one and of all the tests, without exception, indicated a decreased consumption of moist steam when the jackets were working, the effect of the jackets including a decrease in the quantity of steam condensed during admission, a decrease in re-evaporation of water during expansion, and an increase of mean pressure in the cylinders. When variable rates of expansion were employed it was found that the consumption of steam per effective horse-power was larger at the higher rates of expansion, from which the conclusion may be drawn that when cylinders are too large they prevent economy in the consumption of steam.

The second set of trials was made with experimental trains, on ordinary and compound locomotives respectively, with jackets working and not working, but unfortunately as regards these experiments "the great want of success in the attempts to measure the quantity of water condensed in the jackets, as well

as the impossibility of selecting a representative diagram of the mean work of the steam that should be sufficiently accurate for showing the mean power developed in the cylinders during the whole of the test, rendered it hopeless to estimate the effect which the jackets had upon the state of the steam in the cylinders." The comparisons were on this account only available with tests made when the jackets were not at work. The following were the final conclusions arrived at:—For the same consumption of water and fuel per hour, the work done by the compound engine is greater than that done by the ordinary engine; for the same boiler-pressure and the same speed, the increase of work done by the compound engine compared with ordinary engines diminishes in proportion as the total consumption of fuel and water increases.

Mr. Sandiford's experiments were made on two locomotives which had been sent into the shops for heavy repairs, both of them requiring new cylinders. One was arranged with two high- and two low-pressure cylinders, and the other with one high- and one low-pressure cylinder. The compounding of both locomotives was attended with economy in consumption of fuel, and they were decidedly more powerful than the original engines had been, whilst from the drivers' point of view they were not more complicated.

The views held by the members taking part in the discussion agreed generally with those of the authors of the papers as regards the benefits both of jacketing and of compounding locomotives.

After the close of the discussion, the members visited various works in and around London, amongst those most favoured being the Royal Mint, Lambeth Pottery, the Royal Small-Arms Factory (Enfield), the Royal Arsenal (Woolwich), Beckton Gas-Works, the Royal Victoria and Albert Docks, Tilbury Docks, and the Crossness Sewage-Works of the Metropolitan Board of Works.

PROGRESS OF CHEMISTRY AND MINERALOGY

M. FRIEDEL, President of the French Association which met recently at Nancy, gave an address on the progress of chemistry and mineralogy. After briefly referring to the ravages made by death amongst the founders of the Society, and to the prospect of its amalgamation with the Scientific Association of France, M. Friedel proceeded to remark that the progress of chemistry during a period of thirty years had been set forth with masterly clearness and attractive eloquence by the late M. Wurtz at the gathering held at Lille in 1874, and two years later at the Clermont Conference. The theoretical conquests resulting in the discovery of the brilliant coal-tar dyes, the reproduction of alizarin and the other colouring substances of madder, of vanilline (the odoriferous principle of vanilla), of indigo, of the tartaric and citric acids, &c., continue their progressive and pacific career.

The study of countless artificial compounds brings us daily nearer to the natural compounds that have not yet been reproduced, and the most important alkaloids, such as quinine and morphine, seem already almost within the scope of synthetical chemistry. The work that has been undertaken in their regard resembles that of architects engaged in raising stone by stone the plan of some edifice at once of intricate design and difficult access.

This plan once securely established, the reconstruction of the building itself will no longer lie beyond the power of those regular synthetic methods which are daily acquiring greater expansion. It will soon be a mere question of patience and intelligent work, and the time is approaching when quinine and morphine will be produced as readily as alizarin now is. Nay more, there is reason to hope that besides the natural alkaloids others will be obtained endowed with valuable therapeutic properties. While endeavouring to reproduce atropine, whose synthesis he afterwards succeeded in making, M. Ladenburg has obtained homatropine, which produces physiological effects sufficiently distinct to claim, side by side with its homologue, a place amongst the agents employed by oculists. Other less successful essays have also shown in the derivatives of quinoline that patients have perhaps been somewhat prematurely treated with agencies producing a vigorous and very special action on the organism.

If synthetic chemistry has a bright future, we shall also doubtless see the development of another branch of chemistry which has hitherto been comparatively neglected, after having been held in honour at the beginning of the century, and found in Braconnot, of Nancy, an able and devoted cultivator. M. Friedel referred to the research of direct principles, that is to say, of the chemical compounds which exist in animals and plants, and which may be extracted from them. Similar alternatives are often presented in the history of science, which proceeds with irregular leaps, as results from the very nature of things.

The separation of the direct or immediate principles had first to place at the disposal of chemists abundant materials of varied composition, in order to fix their attention on the complexity of organic substances. Then came the time to seek the laws determining their constitution, and now that these laws are sufficiently understood to establish the structure and functions of many of them, the more complete study of their transformations, the more accurate definition of some already determined, the certain discovery of many others still unknown, must attract further attention to the work of those who, like Braconnot, have made a special study of the natural products.

Mineral chemistry has at last succeeded, in the hands of a young and skilful naturalist, in obtaining the isolation of fluorine, which had been in vain attempted by so many other students.

This important result is again due to the process used by Davy for isolating potassium—the decomposing action of the pile. The essay had already been made, but under conditions in which this exceptionally active element reacted on the electrodes or on the vessels. M. Moissan's merit consisted in perceiving that the decomposition should be made at a low temperature, and in the happy choice of the substance to be subjected to the process of electrolysis—hydrofluoric acid made conductive by the addition of fluoride of potassium. In the gaseous current disengaged at the positive pole, crystallised silicium and boron burn at the ordinary temperature, iodide and chloride of potassium are decomposed, mercury and other metals transformed to fluorides, organic compounds carbonised or inflamed, while water absorbs the gas, yielding in its place ozonised oxygen. Thus is produced a large number of reactions, whose study promises a most interesting sequel to this brilliant discovery.

Physico-chemical research continues on its part to furnish means of investigation enabling us to penetrate more deeply into the very life of the chemical molecule, that is, those inner movements whose existence must now be admitted.

Spectroscopy, which has just yielded to M. Lecoq de Boisbaudran two new metals, reveals, by the comparison of the rays, a connection, which is assuredly far from accidental, between the various elements of the same family.

Thermo-chemistry, after having, in the hands of M. Berthelot and M. Thomsen, given the reason of most reactions, now approaches the study of isomeric bodies. M. Bouty's researches on the conductivity of the solutions of salts, and those of M. Raoult on the lowering of the freezing-point of the various solutions, seem to supply fresh means for determining the molecular weight of compounds.

But our attention must now be directed to mineralogy, a far less popular science than chemistry.

After being held in considerable esteem at the close of the last and beginning of the present century, when Werner's labours enabled mineralogists to describe and methodically classify the rich materials accumulated in collections, mineralogy lost its votaries according as it became more scientific. The immortal labours of Haüy, of Berzelius, and the chemical school, seem to have scared the amateurs, who probably saw in mineralogical collections little more than so many picturesque specimens distinguished by their diversified colours and fantastic forms.

Mineralogy presents the special character that it profits by the progress of chemistry and physics, for which it has itself often enough supplied the starting-point. Aiming especially at the description of crystallised minerals, it applies to this description methods which are afterwards profitably transferred to the domain of artificial products.

Thus it has given birth to crystallography, which establishes the laws determining the formation of crystals—those marvellous products of the mineral world in which Haüy recognises the regular aggregations of infinitely minute particles.

This regularity of structure, indicated at once by their outward form, has been confirmed by the study of their many physical properties, especially that of their action on light. From this study has been derived one of the safest and most fruitful processes by which the inward architecture of crystals has

been revealed. This consists in examining their action on polarised light, that is, on light which, by reflection or refraction under suitable conditions, has acquired special properties, and become incapable of being reflected or refracted like ordinary light, except under certain well-defined conditions.

To use a somewhat crude comparison, the luminous ray, after traversing certain media, assumes the appearance of an iron rod that has been passed through a rectangular drawing-frame. If on leaving the frame it meets an opening of like form and size, it will pass through without difficulty; but if the opening be placed crosswise, it can no longer pass.

There is this difference between the rod and the ray—that in all the intermediate positions a portion of the latter will pass through, the quantity increasing according as a more parallel disposition is assumed. Hence, if we take two apparatus corresponding to the frame and the opening, one of which supplies the polarised ray and the other intercepts it at right angles, the result will be complete darkness on the field of the instrument. But if we now place between both a crystalline plate of some substance which does not crystallise in the cubic form, we shall generally see the dark field illumined and often assuming the most lovely colours—an effect due to an action discovered by Arago and explained by Fresnel. With a homogeneous crystal, and when the light falls in parallel pencils on the plate, a uniform tint is diffused over the whole field of the instrument. If the crystal be not homogeneous, but formed of diverse parts jointed or regularly grouped together, but in positions not parallel, we shall get different tints for the different parts. By turning the crystal round, certain coloured strands will be extinguished, as we say, that is, will cease to transmit the light, while others will remain luminous. Hence we have here an extremely delicate and accurate means of studying the structure of crystals in their most intimate details. Haüy had already remarked that all crystals are doubly refracting, except those belonging to the cubic system. Brewster soon after thoroughly established the relation that exists between the optical properties and crystalline symmetry, stating, amongst other points, that cubic crystals alone have no action on polarised light. Nevertheless, observation had shown that certain substances affecting the cubic form had such action, and illumined the obscured field of the polarising apparatus. Biot had even suggested a term to designate, if not to explain, this exception, calling it "lamellar polarisation."

To the researches of M. Mallard we are indebted for the true account of this anomaly, which in fact he has explained away. He shows that the cubic crystals acting on the polarised light are not really cubic, but formed by the regular grouping of parts belonging to other crystalline systems. Boracite, for instance—chloroborate of magnesium usually taking the form of rhombic dodecahedra, that is, a solid of twelve equal rhombs belonging to the cubic system—is formed by the union of twelve straight pyramids with rhombic bases, whose summits unite in the centre of the crystal, and whose bases are the rhombic facets.

M. Mallard's beautiful experiments with parallel rays have been confirmed by those of M. Emile Bertrand with convergent rays, showing in isolated portions of the garnet and of boracite all the properties belonging to regular crystals of orthorhombic substances.

There can be no doubt as to the correctness of the explanation given by M. Mallard of the optical anomalies of crystals which had been regarded as cubic, but which have once more served to illustrate the trite remark, "Trust not appearances."

The optical investigation of crystals, due mainly to the late M. de Senarmont, has become a familiar process which no mineralogist can henceforth afford to neglect.

These same methods, employed with much greater magnification than in Amici and Nörremberg's primitive appliances, also render the greatest services to the geologist in the study of rocks. They enable him to determine with an otherwise unattainable accuracy the minutest elements of these formations, in which minerals are intermingled in diverse proportions. After Sorby, the pioneer in this line of investigation, Zirckel and Rosenbusch in Germany, Fouqué and Michel Lévy in France, have turned to the best account the new method, which has thrown much light on the origin and mode of formation of certain rocks, by showing what substances were first solidified and what parts resisted longest the cooling process.

All these determinations are aided by the study of the optical sign of crystals—that is, the relative velocity with which the two polarised rays are propagated in certain directions—the observation of the position of the axes wherever possible, that of dichroism, and even the approximate measurement of the indices of refraction.

This last has been much facilitated by an instrument recently devised by M. Emile Bertrand. With a transparent or opaque plate of some crystallised substance, and by means of not more than four readings made in two positions of the crystal, we obtain, by the determination of the angle of total reflection, the two or three indices, and consequently the wave-surface of the crystal for all bodies not having too high an index of refraction. And these operations, hitherto impracticable except with prisms or plates of great size, may now be made on extremely small crystals, such as those of rocks.

But however paramount the importance of optical properties, others also claim attention in crystallo-physics. Although of less practical interest in the determination of crystals, they may still open up many new avenues of inquiry to the physicist.

The curious property possessed by some hemihedral minerals of becoming charged with electricity with contrary signs at the two extremities of certain axes when heated or chilled has long been known. MM. J. and P. Curie have now shown that compression on the same crystals acts like the cooling, depression or traction like the heating process. In both cases the phenomenon appears due to the greater proximity or distance of the molecules. It is remarkable that the phemonenon may be reversed, so that hemihedral crystals with inclined facets properly charged with electricity, positive at one and negative at the other extremity, will contract or expand as the case may be.

As regards synthetic mineralogy, it is now known, thanks mainly to the researches of Berthier, Becquerel, Senarmont, H. Sainte-Claire Deville, and Daubrée, that minerals may be reproduced in our laboratories, and that we already possess a valuable means of study, enabling us to understand the conditions in which the natural minerals and their compounds may have been produced. We are thus advancing towards a chemical knowledge of certain species, whose formula analysis alone has failed to establish, and it may even soon be possible to produce useful substances under the very form from which they derive their properties.

The observation of the crystalline products accidentally formed in the metallurgic furnaces first led to this line of study, the firstfruits of which Mittscherlich and Berthier obtained by fusion.

By melting certain silicates, certain rocks or substances with the same chemical composition, and then exposing this vitreous mass to a temperature somewhat lower than that of fusion, MM. Fouqué and Michel Lévy have succeeded in reproducing the identical minerals found in lavas, basalts, and other eruptive rocks. Such are the anorthite and labrodorite feldspars, amphigene, pyroxene, peridot, magnetic iron, &c.

The case is otherwise with the granites, the problem of whose origin is far more difficult to solve. Nevertheless, of their three constituents two have already been artificially obtained.

Quartz had long ago been reproduced by Senarmont by heating gelatinous silica with a solution of hydrochloric acid to about 300° C. But Hautefeuille was the first to obtain fine crystals of orthoclase and albite feldspars by heating silica with alumina and the necessary alkalies in presence of a solvent such as a fused alkaline vanadate or tungstate.

But the conditions of this beautiful experiment do not appear to have been realised in nature. The nearest approach to them was probably the series of essays made by our President jointly with M. Edmond Sarrasin, by heating a solution of alkaline silicate with a precipitated silicate of alumina to nearly 500° C. in a strong steel tube lined on the inside with platinum. According to the alkalies and proportions employed, the result is albite or orthoclase mixed or not with quartz, the crystals resembling those occurring in nature and presenting the same peculiarities of form and grouping. The well-ascertained presence of drops of water in the granitic quartz seems to show that these granites must have been formed in the presence of aqueous solutions. Thus the natural conditions have already been approached, but will not be entirely realised until the hitherto recalcitrant mica has been obtained.

The first essays at reproducing the zeolite group of minerals have been made by De Schulten, who, by heating the silicate of soda in tubes of aluminous glass, has procured small icositetrahedra of analcime, such as occur in the lavas of the Cyclops Islands.

As regards precious stones, the solution of the problem from the scientific, if not the economic, standpoint, was long ago

given for spinel and corundum by Gaudin, Ebelmen, H. Sainte-Claire Deville, and Caron. More recently, MM. Frémy and Feil have prepared the ruby in large crystalline masses unsuitable for cutting, although possessing all the properties of the natural mineral.

Fresh essays seem to have led to more practical results, as for some time past rubies of fair dimensions are met with in the trade, which, although rather less brilliant and transparent, possess the hardness, density, and optical properties of this valuable gem. Several features of their inner structure show conclusively that they were obtained by fusion; in any case it is well known that, unlike silica, which remains vitreous, alumina crystallises by fusion.

The diamond alone appears to have hitherto resisted all attempts at reproduction. Although success in this direction has been frequently announced, the statement has always proved erroneous. The problem is rendered more difficult from the fact that the diamond has nowhere been found in its original lode. This holds good as well for the Brazilian itacolumites and quartzites, and for the serpentine breccias of South Africa, as for the diamantiferous sands. Nevertheless, in the diamond are occasionally embedded some foreign substances, which, while depreciating its commercial value, are very interesting as showing that it must have been formed at a relatively low temperature.

But enough has been said, M. Friedel concluded, to enlist your interest in mineralogy, a science whose progress has been rapid, whose methods are being constantly renewed, and which in every respect deserves the attention of inquiring minds.

SCIENTIFIC SERIALS

American Journal of Science, August.—On hitherto unrecognised wave-lengths, by S. P. Langley. The object of the laborious and delicate operations here fully described has been, not so much to settle the theoretical questions involved in determining the relation between dispersion and wave-length, as to enable future observers to determine the visible or invisible wave-lengths of any heat, whether from a celestial or terrestrial source, observed in any prism. A knowledge will thus be gained of the intimate constitution of radiant bodies, which an acquaintance with the vibratory period of their molecules can usually alone afford. These researches into the whole unexplored region of infra-red energy both from celestial and terrestrial sources have led to the certain determination of wave-lengths greater than 0·005 mm. Radiations have also been recognised whose wave-length exceeds 0·03 mm., so that, while the wave-length known to Newton has been directly measured to nearly eight times, there is probable indication of wave-lengths far greater. The gulf between the shortest vibration of sound and the longest known vibration of the ether has thus in some measure been already bridged over.—On the chemical composition of herderite and beryl, with note on the precipitation of aluminium and separation of beryllium and aluminium, by S. L. Penfield and D. N. Harper. The composition of herderite is shown to be an isomorphous mixture of $CaBeFPO_4$ with $CaBe(OH)PO_4$, which may be written $CaBe(FOH)PO_4$, or a salt of phosphoric acid, two of whose hydrogen atoms have been replaced by a bivalent element, and the third also by a bivalent element whose other free affinity has been satisfied by a fluorine atom or hydroxyl. Chemically it is closely related to wagnerite, triplite, and triploidite, these minerals offering the best illustration of the isomorphism of F and OH. In crystallisation, herderite is orthorhombic, with a prismatic angle of nearly 120°. Regarding water as an essential constituent of beryl, the authors add $\frac{1}{2}H_2O$ to its usually accepted formula, writing it $H_2Be_6Al_4Si_{12}O_{37}$. Its theoretical composition, according to this formula, becomes SiO_2 65·81; Al_2O_3 18·83; BeO 13·71; H_2O 1·65. Specific gravity, 2·706.—Communications from the U.S. Geological Survey, Division of the Rocky Mountains, by Whitman Cross and L. G. Eakins. The present paper deals with ptilolite, a new mineral occurring in cavities of a more or less vesicular augite-andesite, which is found in fragments in the Tertiary conglomerate beds of Green and Table Mountains, Jefferson County, Colorado. It is described as a white substance in extremely delicate tufts and spongy masses composed of short hair-like needles loosely grouped together; hence its proposed name of ptilolite, from the Greek πτίλον = *down*, in reference to the light downy nature of its aggregates. Its empirical formula is $RO,Al_2O_3,10SiO_2 + 5H_2O$, R representing Ca, K_2, and Na_2; it is thus an alumino-silicate of which no previously described hydrate contains so high a percentage of silica. In this respect it may compare with the rare mineral milarite.—Notes on the peridotite of Elliot County, Kentucky, by J. S. Diller. This formation, described as a dark greenish rock with specific gravity 2·781, appears to be undoubtedly of eruptive origin, traversing many thousand feet of palæozoic strata to reach the surface. Its mineralogical composition shows 40 per cent. of olivine, 30·7 serpentine, 14 dolomite, 8 pyrope, 2·2 ilmenite, 2 magnetite, with smaller quantities of biotite, enstatite, octahedrite, and apatite.—Temperature observations at the Lake Superior Copper-Mines, by H. A. Wheeler. The unusually low thermal gradients recorded in these mines—about 1° F. to 100 feet as compared with the normal of 1° F. to 50 or 55 feet in vertical descent, is attributed to the proximity of the cold waters of Lake Superior. The nearer the mines are to this great cooling influence, the lower the thermal gradient will be found to be.—An application of the copper reduction test to the quantitative determination of arsenic, by Henry Carmichael. Using a standard square of copper as an indicator, the author has been led to adopt the method here described, which, for the estimation of small quantities of arsenic in the human system or elsewhere, he believes to be quicker, simpler, more delicate, and, in the hands of toxicologists, less exposed to fallacy, than any other. A copper square 1 millimetre on a side detects ·0000025 grm. arsenious oxide, a quantity 400 times less than that necessary for turning the beam of the ordinary chemical balance.—On the crystallisation of gold, by Edward S. Dana. The paper deals more especially with the delicate crystalline threads and arborescent forms from the White Bull Mine, Oregon, and the specimens of finely crystallised gold from the Californian mines. The crystals are illustrated and fully described.—Classification of the Cambrian system of North America, by Charles D. Walcott. The formations here treated are those characterised by the predominance of the types of Barrande's "First Fauna," and such additional strata, not characterised by the presence of fossils, as are stratigraphically and structurally connected with the Cambrian strata identified by organic remains. These formations, showing a total thickness of over 18,000 feet, with a known fauna of 92 genera and 393 species, are regarded, not as a subdivision of the Silurian, but rather as a well-defined geological system underlying the Lower Silurian (Ordovician) on the North American continent.—Note on the spectrum of Comet *c*, 1886, by O. T. Sherman. When observed with the equatorial of Yale Observatory in May and June, this comet presented no less than seven loci of light where three only are usually seen. These showed approximate wave-lengths 618·4, 600·6, 567·6, 553·7, 517·1, 468·3, and 433·2, besides strongly suspected loci at 545·4, 535·0, 412·9, and 378·6. These are compared with the low temperature spectrum of carbohydrogen, and it is suggested that a chart should be prepared for the carbon compounds at successive heat-levels, after the manner of that drawn up by Lockyer for the photographed spectra of some carbon compounds (*Proc. Roy. Soc.*, xxx. p. 463).

Annalen der Physik und Chemie, Bd. xxviii., No. 7, July 1886.—Th. Schröder, experimental investigation of the influence of temperature upon elastic reaction. The experiments were made with three wires, respectively of silver, iron, and german silver. The elastic reaction was greatest with the first, least with the last of these, and the change in the elastic reaction produced by change of temperature followed the same order.—E. Warburg, remarks on the pressure of saturated vapour. Discusses relation between vapour-pressure and curvature of liquid surface.—W. Fischer, on the pressure of saturated vapours above liquid and above solid substances. The substances chosen were ice and water. The difference, for ice, between the two differential coefficients of pressure with respect to temperature for saturated steam over ice and saturated steam over water is 0·0465, at the melting-point, where the two curves meet. For benzol the two curves do not meet at its melting-point.—A. Schrauf, on dispersion and axial density in prismatic crystals; and on the properties of trimetric crystals. The latter shows the existence of a relation between coefficients of expansion, axial density, and the parameters of the crystal.—A. Toepler, some lecture experiments on waves. A small gas flame is used to show the propagation of a wave of compression in a long tube filled with air, and provided at one end with an india-rubber pear. Several interesting experiments can be shown.—E. Cohn

and L. Arons, conductivity and dielectric constants. An investigation as to whether the dielectric constant of a conductor is infinite, as often stated in text-books. A condenser was arranged to be filled with mixtures of anilin and benzol, xylol, mixtures of anilin and xylol in various proportions, &c., liquids being selected to avoid as far as possible residual charges. The capacities of this condenser were compared with that of an air-condenser, and arrangements were also made to measure the resistances on the bridge. The resistances of the three mixtures of anilin and xylol were 224,900, 1,383,000, and 18,780,000 Siemens's units, and their dielectric constants 1·590, 1·443, and 1·336. The authors conclude from these and other experiments that there is no necessary relation between the two constants; and, further, that the wide differences observed by Hopkinson between the square root of the dielectric constant and the index of refraction in certain vegetable oils cannot be explained by the conductivity.—E. Hoppe, on the theory of unipolar induction: experimental verification of Edlund's theory of the origin in terrestrial magnetism of auroral phenomena.—H. Jahn, on the equivalence of chemical energy and current energy. A discussion of Helmholtz's theory of the secondary heat of a voltaic element.—H. Jahn, on galvanic polarisation. A study of changes of polarisation of certain liquids with changes of temperature, together with deductions verifying Helmholtz's equations.—G. Adler, on the energy of magnetically polarised bodies.—E. Ketteler, addendum on the total reflection of crystals.—F. Koláček, on the gold-leaf spectroscope. An attempt to calculate a calibration of the electroscope from its electrostatic capacity.

THE number of the *Nuovo Giornale Botanico Italiano* for April 1886 contains a number of short articles on various points relating to the flora of different parts of Italy, both phanerogamic and cryptogamic.—Sig. A. Mori describes and figures a singular instance of the production of a pitcher-like structure on the upper surface of a leaf of *Gunnera scabra*.—Dr. O. Mattirolo has examined the "mycorhiza" of the roots of the sweet chestnut, and finds it to furnish a new example of polymorphism among the Hypocreaceæ. It consists largely of two species of fungus, which he names *Melanospora stysanophora* and *M. Gibelliana*. The former is identical with *Stysanus Steminotis* and also with an *Acladium*, and presents an instance of "apandry," or the production of ascospores independently of the previous formation of a male organ. *M. Gibelliana* produces chlamydospores, and also the peculiar structures known as "spore-bulbils," which appear to replace the true ascophorous perithecia.

The most interesting article in the number for July is by Sig. A. Piccone, on the plants growing wild in Liguria which he terms "zoophilous" or "ornithophilous," *i.e.* those which are absolutely dependent for the germination of their seeds on the fruit being swallowed by birds.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, August 4.—Prof. J. O. Westwood, M.A., F.L.S., in the chair.—The following gentlemen were elected Fellows:—Lord Dormer, Messrs. J. H. A. Jenner, James Edwards, Morris Young, F. V. Theobald, E. A. Atmore, and William Saunders, President of the Entomological Society of Ontario.—Mr. Theodore Wood exhibited and made remarks on the following Coleoptera: an abnormal specimen of *Apion pallipes*; a series of *Langelandia anophthalmi*, from St. Peter's, Kent, taken in decaying seed-potatoes; a series of *Adelops wollastoni*, and *Anommatus 12-striatus*, also from decaying seed-potatoes; and a series of *Barypeithes pellucidus*, from the sea-shore near Margate. Mr. Wood also exhibited, on behalf of Dr. Ellis, of Liverpool, a specimen of *Apion annulipes*.—Prof. Westwood exhibited five specimens of a species of *Culex*, supposed to be either *C. cantans* or *C. lateralis*, sent to him by Mr. Douglas, who had received them from the Kent Water-Works. It was stated that they were very numerous in July last, and that persons bitten by them had suffered from "terrible swellings." Prof. Westwood also exhibited some galls found inside an acorn at Cannes in January last.—Mr. Billups exhibited a male and female of *Cleptes nitidula*, taken *in copulâ* in July last, at Benfleet, Essex, on the flowers of *Heracleum sphondylium*. He stated that it was probably the rarest of the twenty-two known species of British *Chrysididæ*, though it had been recorded from the New Forest and from Suffolk.—The Rev. W. W. Fowler announced that a series of specimens of *Homalium rugulipenne* had been received from Dr. Ellis, of Liverpool, for distribution amongst Members of the Society.—Mr. White exhibited a group of three specimens of *Lucanus cervus*, consisting of a female and two males. The female was *in copulâ* with one of the males, which, while so engaged, was attacked by the second male.—Mr. E. A. Fitch read a paper, communicated by Mr. G. Bowdler Buckton, on the occurrence in Britain of some undescribed *Aphides*.—Prof. Westwood read a paper on a tube-making homopterous insect from Ceylon.—Mr. Theodore Wood read a paper on *Bruchus*-infested beans. A discussion ensued, in which Prof. Westwood, the Rev. W. W. Fowler, and Messrs. Weir, Fitch, and Trimen took part.

PARIS

Academy of Sciences, August 16.—M. Fizeau in the chair.—The Secretary announced the loss sustained by the Academy in the death of M. Laguerre, Member of the Section for Geometry, who died on August 13 at Bar-le-Duc. At the obsequies, which took place on August 16, the Academy was represented by M. Halphen.—Remarks on the recent volcanic disturbances in the Northern Island, New Zealand, by M. Emile Blanchard. The author pointed out that this sudden display of igneous activity was a remarkable confirmation of the views already advocated by him in 1882 and 1884 on the subsidence of an austral continent during the modern geological age of the earth. He regarded the New Zealand Archipelago and more or less adjacent islands as a remnant of this continent, or at least of an extensive region, which had existed in a comparatively recent epoch, and he had already, in 1884, anticipated fresh convulsions, such as the tremendous catastrophe of which New Zealand had been the scene after a lengthened period of quiescence. Tarawera and other volcanoes supposed to be extinct have suddenly broken out into fresh activity; lava-streams have overspread vast spaces, and a romantic tract of country, the delight of the early explorers, has been wasted or swallowed up. Although the exact change that has taken place in the aspect of the land cannot be fully known for some time to come, the event already appears as an illustration of still more violent outbursts, which occurred in more or less remote ages. Thus it has been shown in this instance that the inductions drawn from a recently-created science already bear the character of certainty.—On the differential equation of a curve of any order, by Prof. Sylvester. It is shown that a direct and universal solution may be had of the following problem: To find the differential equation of a curve of the order n, where the function of the equation (with unity for constant term), whether U or $(x, y, 1)^n$ is represented under the symbolic form u^n, where $u = a + bx + y$. It is added that the formulas given by M. Halphen in his "Recherches des points d'une courbe algébrique plane," &c., lead to the same results as those here arrived at.—On the employment of intermittent light for the measurement of rapid movements, by M. Gustave Hermite. Indicators of velocity at present in use always absorb a portion of the force of the machine to which they are applied. The author proposes to avoid this inconvenience by the arrangement here described, which, by an ingenious application of intermittent light, enables the observer to measure not only the number of revolutions of any machine, but the velocity of any rapid movement whatsoever, without exercising any mechanical action on the apparatus under examination.—On the mono-substituted haloid derivatives of acetonitril, by M. Louis Henry. The researches undertaken by the author on the functional solidarity and the volatility of the carbon compounds have led him to complete the series of these derivatives. Here he describes mono-ioduretted acetonitril, ICH_2—CN, and monobromuretted acetonitril, $BrCH_2$—CN, reserving for a future communication the comparative study of the mono-substituted haloid derivatives of acetonitril and acetate of methyl.—On the composition of the mineral waters of Bagnères-de-Luchon, Haute-Garonne, by M. Ed. Willm. It is shown that carbonic acid, far from being a negligible quantity in these and similar waters, as was supposed by the late M. Filhol, mostly occurs in a proportion more than sufficient to give a quantity of bicarbonates corresponding to the alkaline property of the water, independently of that which is due to the sulphuret. A complete analysis yielded sulphuric and carbonic acid, chlorine,

silica, ferric oxide, aluminium, sodium, potassium, calcium, magnesium, and traces of iodine, lithium, copper, ammonia, manganese, phosphoric and boric acid, but no arsenic.—Priestley's experiment repeated with aquatic animals and plants, by M. N. Gréhant. The experiment here referred to consists in placing under an air-tight vessel small mammals, such as mice, until the atmosphere becomes vitiated by the absorption of oxygen and liberation of carbonic acid; then, if a sprig of mint be introduced and the vessel exposed to the sun, after a certain time a mouse again introduced will breathe and live freely, the carbonic acid having been decomposed by the chlorophyll under the influence of the light and replaced by oxygen. An analogous experiment is here described with fish, and the leaves of an aquatic plant (*Potamogeton lucens*) introduced into receptacles filled with water.—Atmospheric phenomena observed at Palermo during the recent eruption of Etna, by M. A. Riccò. These light-effects are compared with those following the eruptions of Krakatão and Ferdinandea, their less brilliant character being attributed to the smaller quantity of vapours discharged by Etna.—The telluric currents, their nature, and the part played by them in the production of meteorological phenomena, by M. J. J. Landerer. In this paper, which is supplementary to the communication made to the Academy on October 17, 1881, the author gives the further results of the studies which he has now prosecuted for several years at Tortosa on the telluric currents and their various relations to terrestrial magnetism, the trade-winds, the solar spots, and the like.

BERLIN

Chemical Society, June 21.—A. W. Hofmann, Vice-President, in the chair.—Prof. Scheibler described in a long and very interesting paper his new methods of obtaining a product rich in phosphorus from the crude slag produced in Thomas's process. Whilst formerly the slag was extracted with dilute hydrochloric acid, and a precipitate rich in phosphorus obtained by adding lime to the solution, the present price of hydrochloric acid rendered it desirable to simplify the process. It was at first attempted to do this by a fractional solidification of the fused slag, the portion first solidifying containing little phosphoric acid, whilst the liquid portion separated from it furnishes an excellent material for manure. An essentially better method consists in adding the lime to the iron, not all at once, but first of all about two-thirds of the necessary quantity; the slag produced is then removed, the remainder of the lime added, and the process completed. The first lot of slag obtained in this way contains about 31 per cent. phosphoric anhydride, and 58 per cent. lime, whilst the second lot contains but little phosphorus, though it is rich in iron, of which it contains 24 per cent., the first slag having only 1·8 per cent. The second slag is returned to the furnaces used in the production of crude iron. The advantages of the method are a shortening of the blowing operation, the possibility of increasing the charge, a more complete removal of the phosphorus, less loss of iron, and considerable saving of lime. Further advantages are that the first portion of the slag forms a valuable manure, whilst the second portion is used again in the furnaces. The paper concludes with a discussion of the importance of this more complete separation of the phosphorus from iron ores for agricultural purposes.—W. Will exhibited an aromatic ketone obtained from the root of *Pæonia Moutan*, and which has been more closely examined by Prof. Nagai, of Japan. Its composition is

$$C_6H_3\begin{cases}COCH_3 & (1)\\ OH & (2).\\ OCH_3 & (4)\end{cases}$$

—There were two papers by J. Traube: (1) on the size of maximum-drops of the ordinary alcohols and fatty acids, and their aqueous solutions; and (2) on the dependence of the size of drops on external influences.—K. Polstorff has found that East Indian bolarrhena contains conessine, and he considers that this alkaloid is identical with Haines's wrightine.—K. Heumann and E. Mentha have studied the behaviour of monochlorazo- and hydrazobenzene to acids; the latter yields chlorazobenzene, parachloraniline, and aniline.—Piutti has obtained a new asparagin from vetch sprigs; its aqueous solutions are dextrorotatory, and its compounds have the same rotatory power as the corresponding compounds of ordinary asparagin, but the rotation is always in the opposite direction.—T. Salzer described a new method of obtaining pentathionic acid by oxidising a solution of sodium thiosulphate with iodine in the presence of potassium arsenite.—M. Lange described a new synthesis of mixed azo-dyes from aromatic diamines.—G. Ciamician and P. Silber have studied the action of pyrroline on alloxan, and have described the properties and derivatives of pyrrolalloxan, $C_8H_7N_3O_4$, which results from the reaction.—J. Schmid showed that the colouring-matter of fisetwood (*Rhus cotinus*, L.), is not identical with quercitine, and that it is present in the plant as a glucoside (*fustin*); he described the preparation and the ethyl- and acetyl-derivatives of fisetin.

STOCKHOLM

Geological Society, April 1.—Prof. W. C. Brögger gave an account of the volcanic rocks extending between Langesund, in the Christiania Fjord, and Lake Mjösen, in Central Norway, founded on earlier and his own researches, the latter extending over many years. He had come to the conclusion that the whole basin was due to an erosion of the earth's crust, which had forced up the volcanic matter. The oldest of these, the augite porphyry, had been discharged in the form of lava streams over the Devonian surface of the earth. The more recent ones had not reached the surface, but had hardened at lower depths, and had become disclosed at a later date.—Herr A. E. Törnebohm described the remarkable coal-bearing rock which was discovered by Igelström some twenty years ago in the crystalline slates of the fundamental rock at the Nulla Mountain, in the province of Varmland. His microscopical researches went to show that the coal had been introduced into the rock whilst the formation of feldspar was still in progress.

CHEMICAL PHYSICS

Elements of Chemical Physics. By Josiah P. Cooke, Jr., Erving Professor of Chemistry and Mineralogy in Harvard University. Fourth Edition. (London: Macmillan and Co., 1886.)

THE preface to this work bears the date Feb. 1, 1860; no explanation is given of the issue in 1886 of a *fourth* edition in the form before us. According to the dictionary, an edition is "the whole number of copies of a work published at once." We are forced to assume that such a definition would be accepted as sufficient by Prof. Cooke; but in the case of educational works dealing with a branch of science which is daily enriched by new discoveries, the reading public are in the habit of supposing that a *new* edition is not a mere reprint of the former edition: it is rightly expected that it shall take notice of, at all events, the more important of recent discoveries, and failure to recognise this elementary truth is unpardonable.

It is a grave injustice to put into the hands of the innocent student a book dated 1886 which was first issued in 1860, and without informing him that he is to learn nothing of the classical discoveries in chemical physics made during the past quarter of a century: on advancing to do battle in the ranks of science he would be about in the position of our old wooden walls in face of modern ironclads and torpedo-boats.

The work is divided into five chapters, the first (9 pp.) being introductory. Chapter II. (107 pp.) deals with the general properties of matter; Chapter III. (309 pp.) is on the three states of matter; heat is the subject of Chapter IV. (235 pp.); and Chapter V. (24 pp.) is on weighing and measuring. The volume is intended—according to the 1860 preface—to furnish a full development of the principles involved in the processes of weighing and measuring small quantities of matter; subsequent volumes were to treat on light in its relations to crystallography; on electricity in its relations to chemistry; and on stoichiometry and the principles of chemical classification; but we are not aware of their issue. Unlike most text-books, it is a most readable work, containing much interesting matter, and is admirably printed; hence it is particularly to be regretted that it presents so imperfect and antiquated an account of the subjects treated of. In justification of this statement we may point out that the latest reference to experiments on the condensation of gases is to those of Natterer. Andrews's great discovery of the critical point is nowhere referred to. Regnault's determinations of the specific heat of carbon in its three forms are quoted, but not a word is said of Weber's important investigation on this subject; in the section in which the methods of determining specific heat are described no reference is made to Bunsen's beautiful method; and the word dissociation nowhere occurs, the classical discoveries of Deville and his school being unmentioned. One inaccuracy requires special mention. We are told (p. 428) that, "According to the modern theory of chemistry, equal volumes of all substances in the state of gas contain precisely the same number of molecules, *or, what amounts to the same thing, the molecules of all bodies in the state of gas occupy exactly equal volumes.*" The latter part of the sentence, which we have italicised, is obviously unmitigated nonsense, yet it is a statement which perpetually haunts us. A well-known standard text-book of chemistry from which probably a very large proportion of our youth gain inspiration in fact tells us almost in the same words that "the relation existing between the volumes of gases when they combine together has been found to be a very simple one, inasmuch as the densities of all elements known in the gaseous state are identical with their atomic weights; *or, what is the same thing, the atoms in the gaseous state all occupy the same space* (Gay Lussac, Avogadro)." Could anything be more misleading and inaccurate, since mercury, phosphorus, sulphur and iodine are all known "in the gaseous state"? It cannot be too clearly stated that the *chemist* only concerns himself with the *relative weights* of atoms and molecules, and that Avogadro's law only has reference to the *relative numbers* of molecules in equal volumes of gases, their size being altogether left out of account: no notice being taken, in fact, of the space which the stuff itself occupies. Our notions on the subject of the size of molecules and atoms are of the very vaguest at present, and even Sir William Thomson has not ventured, we believe, to consider the differences in size of molecules of different kinds: for the most part they certainly cannot be of the same size. The popular method of teaching the volumetric relations between gases is probably the cause of the error now referred to being steadily perpetuated. The ordinary student more often than not will insist—very naturally—in regarding the term volume as representing a specific quantity: being taught, moreover, to consider the symbol of a compound gas as equivalent to "two volumes," he extends the idea of volume to the elementary symbols and naturally enough concludes that if I_2, for example, represent *two* volumes, I must represent *one* volume; hence it is difficult to make him realise that a change such as is represented by the equation $I_2 = I + I$ involves a doubling of the volume. Again, the common practice of speaking of compound gases as *containing* certain volumes of the constituent gases is both misleading and inaccurate: for example, it is found that the gaseous density of phosphorus is such that its molecular composition is expressed by the formula P_4: this represents "two volumes," and so the symbol P is said to represent "half a volume," and we are then gravely told that "two volumes" of phosphuretted hydrogen *consists* of or *contains* "three volumes" of hydrogen and "half a volume" of phosphorus. Some teachers engrave the error still more deeply upon the student's mind by performing before him a kind of Jack-in-the-box trick, picking out from a box on which the symbol of the compound is painted a series of boxes which in number and size are supposed to represent the volume of the elements contained in the compound. All that we really know is that a given bulk of a particular gas will decompose into, or can be formed from, certain bulks of the constituent elements: that phosphuretted hydrogen, to take the example cited, on decomposition yields one and a half times its bulk of hydrogen and half its bulk of phosphorus gas. The

only method by which we could endeavour to form any estimate of the relative volume occupied in a compound by the constituent atoms would be by taking the molecular volume of the compound and the atomic volumes of the constituents into account; but this is never done. It would be a great advantage if we were to cease using the term *volume* when speaking of gases, and were to treat all questions concerning changes in volume from a dynamical point of view: Avogadro's law tells us, in fact, that, in every change in which gases are concerned, the variation in the space required to contain the gases—pressure and temperature remaining constant—will be directly as the variation in the number of gaseous molecules. If the equation be written which expresses the change, care being taken to employ the symbols which represent the molecular composition of the gaseous substances concerned in it, it is merely necessary to add up the number of molecules of the gaseous substances appearing on either side: the two sums will give the ratio of the volumes before and after change. By our present practice thoroughly false conceptions are engendered: a fundamental principle of our science is most unscientifically taught: and yet when we come to examine we marvel at the stupidity displayed by the examinee when dealing with simple questions of volume change!

It will be in place here to inquire What is *chemical physics?* To judge from the books on the subject, we are probably justified in defining it as a milk-and-watery kind of physics specially prepared to suit the weak digestion and small appetite of the embryonic chemist; as a spineless kind of physics—physics without the solid backbone of mathematics. It is high time that it were recognised that he who wishes to be a chemist, and not the mechanical automaton who too frequently in this country goes by the name, must study physics seriously and properly: a mere smattering is of very little use. It is now incontestable that the sciences of chemistry and physics are inseparable: indeed the whole system of modern chemical theory reposes on a purely physical basis—that of Avogadro's law; and of late years the opinion has undoubtedly gained ground that the study of the physical attributes of pure elements and compounds must be carried on systematically and at the same time that their strictly chemical attributes are investigated, if we are ever to penetrate the veil of mystery which at present enshrouds the simplest chemical phenomena. Much work has already been done, and it is greatly to the credit of chemists that it has nearly all been executed by chemists who have been at the pains to study physical methods. Physicists have contributed comparatively little to the advancement of chemical physics, and it is undeniable that not a few investigations of importance to chemistry executed by physicists with the precision in measurement which characterises modern physical inquiry, are to a large extent labour spent in vain, as no guarantee has been given of the purity of the materials employed. Parenthetically it may be added that the physics as well as the chemistry of *pure* substances are fields of inquiry all but untrodden: the study of *pure* materials is *the* work of the future; and it is safe to say that when the results are recorded they will differ in many and important particulars from those now accepted. It is perhaps not undesirable to point out that a true conception of the meaning of the word *pure* does not always appear to be present in the mind of the chemist or physicist, otherwise the expression "chemically pure" would not so frequently occur. What is meant thereby, we presume, is that the substance is so nearly pure that the amount of impurity present does not perceptibly affect the results of quantitative analysis; but the amount of impurity present in a substance in such a case may exercise a most important influence on its chemical behaviour, and may also materially modify some of its physical properties. If, instead of distinguishing degrees of impurity, we continue to make this somewhat improper use of the word pure, it will be desirable also to speak of substances as being "spectroscopically pure," "electrically pure," &c., to indicate the nature of the test which they will pass.

To conclude, a book worthy to be called a treatise on chemical physics has yet to be written. It should contain a sufficiently detailed account of exact methods of determining the various physical attributes and the trustworthy results thus far recorded, together with a discussion of the bearing of these results on the problems of chemistry. It could hardly be the work of a single individual, but would doubtless require the co-operation of chemist and physicist. No mere compilation will suffice: to be of value it must be subject to the control of a chemist who is master of his science. Such a work would of necessity be of enormous service to students; and it would exercise an important influence on the progress of our science. HENRY E. ARMSTRONG

OUR BOOK SHELF

Madagaskar, und die Inseln Seychellen, Aldabra, Komoren, und Maskarenen. By Prof. Dr. R. Hartmann. (Leipzig and Prague, 1886).

THIS little work forms the fifty-seventh volume of "Das Wissen der Gegenwart," a scientific series which has already done so much for the spread of useful and accurate information amongst the Germanic populations. The author, himself personally acquainted with some of the localities here described, gives as clear and comprehensive an account of the various insular groups in the Indian Ocean as was possible within the available space of 150 pages. Of this space over two-thirds are devoted to Madagascar, whose physical constitution, natural history, ethnology, and political relations are treated with great ability. The best authorities, such as Grandidier, Shaw, Richardson, Sibree, and Hildebrandt, have been carefully consulted, and room has even been found for the discussion of such controversial questions as the existence of Sclater's vanished Lemuria, the origin of the Malagasy people, the affinities of their language, the presence in the island of the Vazimba and other aboriginal non-Malayan and Negrito tribes. Dr. Hartmann is inclined to accept the statements made by Commerson and Modave regarding the woolly-haired and dwarfish Kimo people of the southern districts, and suggests possible affinities either with the South African Bushmen or the Andamanese and Aeta Negritos of the Philippine Islands. The Malagasy he regards as essentially a mixed race, Polynesian, Malay, and African (especially Galla and Somali) elements being found diversely intermingled amongst the Hovas, Sakalavas, Betsimisaracas, and other native communities. The Comoros, Seychelles, and Mascarenhas (Mauritius, Réunion, and Rodriguez)

archipelagoes are treated with equal thoroughness, and the work is provided with a map of the Indian Ocean, an index, and numerous well-executed woodcuts.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Physiological Selection and the Origin of Species

IN the *Journal* of the Linnean Society (Zoology, No. 115, 1886, p. 350, footnote) Mr. Romanes says: "I cannot find that any previous writer has alluded to the principle which it is the object of the present paper to enunciate, and which is explained in the succeeding paragraphs."

But in the fourth edition of the "Origin of Species" (1866), p. 311,[1] the following passage occurs, in which the main idea of "physiological selection" is clearly alluded to.

"It may be admitted, on the principle above explained, that it would profit an incipient species if it were rendered in some slight degree sterile when crossed with its parent-form or with some other variety; for thus fewer bastardised and deteriorated offspring would be produced to commingle their blood with the newly-forming variety."

The author then goes on to show that, as he believed, this kind of sterility could not be increased by natural selection—a discussion with which I am not now concerned. I have other evidence to show that my father was familiar with the principle of physiological selection, and, moreover, that he did not regard it with any great favour.

In Mr. Belt's "Naturalist in Nicaragua" (1874), a suggestion is made, identical with that of Mr. Romanes in the Linnean *Journal*. Mr. Belt says (p. 207):—"The varieties that arise can seldom be separated from the parent form and from other varieties until they vary also in the elements of reproduction. . . . As long as varieties interbreed together and with the parent form, it does not seem possible that a new species could be formed by natural selection, excepting in cases of geographical isolation. All the individuals might vary in some one direction, but they could not split up into distinct species whilst they occupied the same area and interbred without difficulty. Before a variety can become permanent, it must either be separated from the others or have acquired some disinclination or inability to interbreed with them. As long as they interbreed together, the possible divergence is kept within narrow limits, but whenever a variety is produced the individuals of which have a partiality for interbreeding, and some amount of sterility when crossed with another form, the tie that bound it to the central stock is loosened, and the foundation is laid for the formation of a new species. Further divergence would be unchecked, or only slightly checked, and the elements of reproduction having begun to vary, would probably continue to diverge from the parent form, for Darwin has shown that any organ in which a species has begun to vary is liable to further change in the same direction. Thus one of the best tests of the specific difference of two allied forms living together is their sterility when crossed, and nearly allied species separated by geographical barriers are more likely to interbreed than those inhabiting the same area."

In my copy of Belt's book the words "No, No," are pencilled in my father's handwriting on the margin, opposite the sentence "All the individuals might vary in some one direction, but they could not split up into distinct species whilst they occupied the same area and interbred without difficulty."

Cambridge, August 27 FRANCIS DARWIN

NEITHER Mr. Galton nor Mr. Meldola have had time or opportunity to consult my original paper before writing their comments on the NATURE abstract. I will, therefore, consider those of their remarks which have been anticipated in the paper.

Mr. Galton writes:—"It has long seemed to me that the primary characteristic of a variety resides in the fact that the individuals who compose it do not, as a rule, *care to mate* with those who are outside their pale, but form through their own sexual inclinations a caste by themselves." Now, I have fully recognised this principle as one among several others which is accessory to, although independent of, physiological selection: see L.S. paper, p. 377, where also reference is given to the "Origin of Species," showing that this factor was likewise recognised by Mr. Darwin as one of importance in the prevention of intercrossing. But, inasmuch as this factor—which may be called psychological selection—can only apply to the case of the Vertebrata,[1] I am disposed to think that it is of much less general importance than the other factors which I have mentioned as accessory to physiological selection, and which, taken altogether, furnish a complete theoretical explanation of the fact that sterility between natural species is not invariably absolute, but occurs in all degrees. For, "in all these cases where the principles of physiological selection have been in any degree accidentally assisted by other conditions, a correspondingly less degree of variation in the reproductive system would have been needed to differentiate the species" (p. 377).

Thus far, therefore, Mr. Galton is really in full agreement with me. But he goes on to say:—"If a variety should arise in the way supposed by Mr. Romanes, merely because its members were more or less infertile with others sprung from the same stock, we should find numerous cases in which members of the variety consorted with outsiders." But how can we possibly know that such is not the case? If my theory is true, it must follow, as Mr. Galton says, that such unions would be more or less sterile, and, as this sterility is itself the only variation which my theory supposes to have arisen *in the first instance*, *ex hypothesi* we can have no means of observing whether or not the individuals which present this variation "consort with outsiders," or with those individuals which do not present it. Lastly, in as far as it is true that "we hardly ever observe pairings between animals of different varieties when living at large in the same or contiguous districts," the fact in no way makes against my theory of physiological selection: it only serves to supplement this theory, in the case of higher animals, by what I regard with Mr. Galton as the proved facts of psychological selection.

The letter by Mr. Meldola is a masterpiece of Darwinian thinking, and on this account I am glad to find myself much more in agreement with him than he appears to suppose. For when he reads my full paper he will see that I have taken precisely the same view upon natural selection as a possible cause —or, rather, accessory promoter—of specific sterility as that to the statement of which the larger part of his letter is devoted. I may remark, however, that of all parts of my paper I regard this as the most speculative and least secure. And this, first, because Mr. Darwin himself, after profound meditation upon the subject, came to the conclusion that natural selection could not operate so as to induce sterility; and, next, because the supposition that it does so operate involves one of the most difficult and complex questions in the whole philosophy of evolution—namely, whether it is possible for natural selection to modify an entire *type* without reference to benefit of its constituent *individuals*. Now, although for reasons which need not here be detailed, I have been led, like Mr. Meldola, to take a different view from that of Mr. Darwin, and to conclude that natural selection may benefit the type without reference to the individual, still I regard this conclusion as so highly speculative that I am glad to think the much more certain theory of physiological selection is not vitally affected either by its acceptance or its rejection. If it is true that natural selection may be able to modify an organic type (as my critic and myself agree in arguing, the type in this case being a variety) by conferring on it the benefit of sterility with its parent form, notwithstanding that this cannot be effected through benefit conferred on any of the constituent individuals, then all we have to say in the present connection is that natnral selection is probably one of the many other causes which lead to physiological selection.

[1] A corresponding but not identical passage occurs in the sixth edition, p. 247.

[1] This, at least, is what I state in the paper. Mr. Galton, however, suggests that the principle may be extended even to plants, through "the selective appetites of the insects which carry the pollen." This suggestion is unquestionably original, and bears the stamp of its author's ingenious mind. Moreover, considerable probability is, I think, lent to the suggestion by the observations of Mr. Bennett and others on individual insects selecting similarly coloured flowers on which to feed (see *Journ. L.S.*, 1883).

On the other hand, if natural selection cannot thus operate, all we have to say is that there still remain many other causes adequate to explain the occurrence of physiological selection—to wit, those causes which are concerned in the occurrence of variation in general.

The essay by Prof. Weismann on the influence of isolation, to which Mr. Meldola refers, is so replete with facts and arguments unconsciously bearing on my theory, that in writing my preliminary paper it appeared advisable to reserve so rich a mine for subsequent working out in detail. In my paper, therefore, I have merely alluded to Prof. Weismann as one among the comparatively few evolutionists who have hitherto sufficiently considered the influence of independent variation (or the prevention of intercrossing) in the evolution of species.

It only remains to consider Mr. Meldola's extremely able criticism of my view that natural selection ought not in strictness to be regarded as a theory of the origin of species, but rather as a theory of the development of adaptive modifications. My argument is that natural selection can only be a theory of the origin of species in so far as species differ from one another in points of utilitarian significance; and that even then it is only a theory of the origin of species, as it were, incidentally: the *raison d'être* of natural selection is in all cases that of evolving adaptations (whether these be characteristic of species only, or likewise of higher taxonomic divisions); and if in some cases the result of performing this function is that of raising a variety into a species, such a result is merely collateral, or, in a sense, accidental. No doubt if species always and only differed from one another in points of utilitarian character, the collateral nature of the result might be disregarded, and the theory would become a theory of the origin of species in virtue of its being a theory of the development of adaptations. But, as a matter of fact, species are very far from being always and only distinguished from one another in points of utilitarian character, and in so far as they are not thus distinguished natural selection is obviously in no sense a theory of the origin of species. Again, and more particularly, the one feature which more than any other serves to distinguish species from species is that of mutual sterility, and it would be a bold flight of speculation to affirm that this has been in all cases the result of natural selection, when even Mr. Darwin was reluctantly compelled to conclude that such could not be the result of natural selection in any case. On the other hand, my theory of physiological selection explains this very general feature of specific distinction quite independently of natural selection; and then goes on to show that, when once this primary distinction has arisen, many others of a secondary kind will ensue, both with and without the assistance of natural selection.

Now, the objection which Mr. Meldola adduces against this argument is that I have not proved physiological selection to be independent of natural selection. In other words, he does not dispute the probable truth of my theory; but he says that, granting its truth, it is still only "one particular phase of natural selection." But surely the burden of proof here lies on the side of my critic. If he can show any sufficient reason for going much further than I have ventured to go in out-Darwining Darwin—or for holding that natural selection may not merely help in inducing sterility in some cases, but has been the sole cause of it in all cases—then I should welcome his proof as showing that the principles of physiological selection ultimately and in all cases rest on those of natural selection. But, clearly, it is for him to prove his positive: not for me to prove what I regard as an almost preposterous negative.

So much for the main criticism. But he adds this rider, namely, that, as the struggle for existence is always most severe between the most closely related forms, unless the new or sexually protected form arising under physiological selection possesses some distinct advantage over the old or parent form, it will be exterminated by the latter quite as effectually as it would be by intercrossing in the absence of physiological selection. To this I may answer in the words of my full paper:—"So long as there is no actual *detriment* arising to the variety on account of its being sexually separated from the parent, any ideas derived from the theory of natural selection are plainly without bearing upon the subject" (p. 406). In other words, so long as in all other respects of organisation the sexually separated variation is not less "fit" than its parent stock, so long there is no reason to anticipate any disadvantage in the struggle for existence. And forasmuch as the sexual separation arises only by way of a variation locally affecting the reproductive system, when the variation is first sexually separated, it will in all other respects resemble its parent stock, and so be able to compete with it on equal terms—mere numerical inferiority being without significance where intercrossing is prevented. It was in order to convey this meaning that I proposed as an alternative name of my theory, "Segregation of the Fit"; seeing that before any physiological segregation can take place there must be organisms to be segregated, and that unless these organisms had already proved themselves fitted to survive in the struggle for existence, in existence they could not be. But I do not call physiological selection "Segregation of the *Fittest*," because, unlike natural selection, it is in no way concerned with the principle of conflict. So long as the organisms which have been separated by physiological selection are sufficiently fit to have previously passed muster at the hands of natural selection, there is no reason why the daughter type should be fitter than the parent.

But, so far as I can see, the only material point of difference between Mr. Meldola and myself consists in his regarding physiological selection as "subordinate" to natural selection, while I consider the two as quite independent principles, although, as explained in my paper, I believe that they frequently and in several ways play into each other's hands.

Earth-Currents and Aurora

THERE appears to have been a very remarkable and widespread earth-current storm on March 30 last, full particulars of which it would be extremely useful to have on record. My attention has been drawn to this storm through witnessing, on the evening of that day, one of the most vivid and interesting displays of the aurora that I have ever seen. Mr. G. H. Kinahan, writing in NATURE for April 8 (p. 537), describes the same aurora as observed by him in Donegal between 8 and 9 p.m., and notes its peculiar bright silvery type. It must, however, have been a far less imposing display at Donegal, where the weather was less favourable, than at Kingstown, where I saw it between 9 and 10 p.m., the most brilliant display occurring between 9.30 and 9.45 p.m. From the northerly horizon there rolled up to the zenith in quick succession streams and masses of white light, until the whole face of the sky to the north and west was illuminated with swiftly mounting flames of silvery whiteness and wonderful beauty. A correspondent in NATURE for April 15 (p. 559) describes the same aurora witnessed by him between 8 and 11 p.m. on March 30, at Konigsberg, in Prussia.

According to the *Electrician* (April 2, p. 404), on the morning of March 30 a violent earth-current storm occurred in London, stopping all telegraphic work for some time. During the same day strong earth-currents are reported on the Mediterranean cables, and in the afternoon of that day (March 30) this terrestrial electric storm had reached India, lasting from 2 to 5 p.m., and stopping work on the Bombay and Madras line. At the same time powerful earth-currents are reported on the Madras and Penang cable, causing work over it to be stopped from 3 till 7 p.m. on March 30. Similar disturbances are reported on the Java cable, beginning the same afternoon, and becoming fainter on all lines at 10 p.m. Recently an account has been published of a great earth-current storm on the China and Japan cable on March 30, and a diagram of the perturbations produced on that line is given in the *Electrician* for August 6. The storm began between 4 and 5 p.m., Shanghai time, on March 30, and lasted till 11 p.m. that day, the maximum strength of the earth-current on the cable occurring between 6 and 7 p.m. being then equal to 3·6 milliamperes. Smaller renewals of the storm took place both in Europe and Asia on the morning of March 31.

Perhaps some of the readers of NATURE can give further details of this extensive storm, and it would also be useful to have on record the magnetic perturbations noticed on this occasion in different localities, and the time of their occurrence.

Chlamydomyxa in the Engadine

YOUR readers will be interested to hear that I have found here in Pontresina the very interesting Protozoon described twelve years ago, in the *Quarterly Journal of Microscopical Science*, by

Mr. Archer, of Dublin, under the name Chlamydomyxa. Mr. Archer obtained his specimens crawling upon, and into, the tissues of the bog-moss (Sphagnum) in moor-pools in Westmeath (so far as I recollect). He often found it in a spherical condition, encysted in a cellulose envelope, and more rarely expanding into a most curious network of fine protoplasmic threads, upon which were observed very numerous oblong corpuscles, which slowly travelled along the threads, thus recalling the structure of Labyrinthula described by Cienkowski.

No one has found Archer's Chlamydomyxa, or been in a position to confirm independently his description, up to the present date. He has kindly sent to me *encysted* specimens of the Chlamydomyxa, but these would not leave their cysts and exhibit the characteristic network and corpuscles; and others whom he has wished to oblige by a sight of this interesting organism have also, I believe, failed to obtain the characteristic phase.

I have from time to time searched for Chlamydomyxa when I have been in a moorland region and had my microscope with me, but have hitherto failed to find it. It was not, therefore, with any great amount of confidence that I gathered some brownish tufts of Sphagnum from a small ditch (with slowly-running water) in a clearing in the pine-wood behind the tennis-court at Pontresina, and brought them to the hotel to search them for Chlamydomyxa. But I found a number of yellowish spheres about 1/150 inch, and less in diameter, which excited my suspicions. After a brief delay these began to throw out protoplasmic filaments, and soon around each was a wonderful series of branching stems of protoplasmic threads, reaching far away from the central yellow granular body and in the most varied directions. Along the threads minute oval corpuscles slowly streamed. There is no doubt that this organism belongs to Archer's genus Chlamydomyxa, and probably enough is specifically distinct from that which he found in Ireland. It is extremely abundant in the Swiss locality.

From what I have seen of Chlamydomyxa, I am now inclined to admit that it is *less* closely related to Cienkowski's Labyrinthula than I had previously supposed. The moving corpuscles of Cienkowski's organism are very much larger bodies than are the ovoid corpuscles of Chlamydomyxa.

Pontresina, August 23 E. RAY LANKESTER

THE BRITISH ASSOCIATION

THE fifty-sixth annual meeting of the British Association was opened in Birmingham last night, when Lord Rayleigh resigned the Presidential chair to Sir William Dawson, Principal of McGill College, Montreal. The attendance at the fourth Birmingham meeting promises to be much above the average, and so far as the Birmingham people are concerned everything has been done to secure success. All the new public buildings, including Mason College and the fine new Art Gallery, have been placed at the disposal of the Sections. The reception-rooms, reading-rooms, writing-rooms, and other general rooms, not omitting the smoking-room, are all that could be desired. All the leading clubs of the town have been thrown open to members; facilities have been given for visiting the various manufactories in the town and neighbourhood; the industrial exhibition in Bingley Hall has been admirably arranged; while there is a formidable programme of social entertainments and excursions. Among the foreign visitors expected, one of the most distinguished is Prof. Haeckel. There is a very large representation, moreover, of colonial science.

The Local Committee have prepared a very excellent Hand-Book of Birmingham for the use of the visitors, the various sections of which are written by specialists. After a General Introduction by Mr. G. J. Johnson, Part 1 deals with Old Birmingham, by Mr. S. Timmins. The various aspects of Modern Birmingham are treated of by different writers. The section on Art is by four specialists, and the Manufacturing Industries are described by Mr. C. J. Woodward. Part 3 is devoted to Geology and Physiography, and is edited by Prof. C. Lapworth, who has been assisted in the various sections by several local geologists. Part 4, dealing with Zoology, is edited by Mr. W. R. Hughes, F.L.S., who also has had the assistance of various local specialists; so with the Botany, edited by Mr. W. Mathews. The appendix comprises a variety of curious and useful information, while a pocket contains a useful sketch-map of the Geology of the Birmingham district, by Prof. Lapworth. It will thus be seen that the Hand-Book, while well adapted for its special purpose, is likely to be of permanent value.

INAUGURAL ADDRESS BY SIR J. WILLIAM DAWSON, C.M.G., M.A., LL.D., F.R.S., F.G.S., PRINCIPAL AND VICE-CHANCELLOR OF MCGILL UNIVERSITY, MONTREAL, CANADA, PRESIDENT

TWENTY-ONE years have passed away since the last meeting of the British Association in this great central city of England. At the third Birmingham meeting—that of 1865—I had the pleasure of being present, and had the honour of being one of the Vice-Presidents of Section C. At that meeting my friend John Phillips, one of the founders of the Association, occupied the Presidential chair, and I cannot better introduce what I have to say this evening than by the eloquent words in which he then addressed you:—"Assembled for the third time in this busy centre of industrious England, amid the roar of engines and clang of hammers, where the strongest powers of nature are trained to work in the fairy chains of art, how softly and fittingly falls upon the ear the accent of Science, the friend of that art, and the guide of that industry! Here where Priestley analysed the air, and Watt obtained the mastery over steam, it well becomes the students of nature to gather round the standard which they carried so far into the fields of knowledge. And when on other occasions we meet in quiet colleges and academic halls, how gladly welcome is the union of fresh discoveries and new inventions with the solid and venerable truths which are there treasured and taught. Long may such union last; the fair alliance of cultivated thought and practical skill; for by it labour is dignified and science fertilised, and the condition of human society exalted." These were the words of a man who, while earnest in the pursuit of science, was full of broad and kindly sympathy for his fellow-men, and of hopeful confidence in the future. We have but to turn to the twenty Reports of this Association, issued since 1865, to see the realisation of that union of science and art to which he so confidently looked forward, and to appreciate the stupendous results which it has achieved. In one department alone—that to which my predecessor in this chair so eloquently adverted in Aberdeen, the department of education in science—how much has been accomplished since 1865. Phillips himself lived to see a great revolution in this respect at Oxford. But no one in 1865 could have anticipated that immense development of local schools of science of which your own Mason College and your admirable technical, industrial, and art schools are eminent examples. Based on the general education given by the new system of Board-schools, with which the name of the late W. E. Forster will ever be honourably connected, and extending its influence upward to special training and to the highest University examinations, this new scientific culture is opening paths of honourable ambition to the men and women of England scarcely dreamed of in 1865. I sympathise with the earnest appeal of Sir Lyon Playfair, in his Aberdeen address, in favour of scientific education; but, visiting England at rare intervals, I am naturally more impressed with the progress that has been made than with the vexatious delays which have occurred, and am perhaps better able to appreciate the vast strides that have been taken in the direction of that complete and all-pervading culture in science which he has so ably advocated.

No one could have anticipated twenty years ago that a Birmingham manufacturer, in whose youthful days there were no schools of science for the people, was about to endow a College, not only worthy of this great city, but one of its brightest ornaments.[1] Nor could any one have foreseen the great development of local scientific Societies, like your Midland Institute and Philosophical Society, which are now flourishing in every large town and in many of those of less magnitude. The period of twenty-one years that has elapsed since the last Birmingham meeting has also been an era of public museums and laboratories for the teaching of science, from the magnificent national

[1] It was in 1865 that Sir Josiah Mason was, quietly and without any public note, beginning to lay the foundation of his orphanage at Erdington

institutions at South Kensington and those of the great Universities and their Colleges down to those of the schools and field-clubs in country towns. It has besides been an era of gigantic progress in original work and in publication—a progress so rapid that workers in every branch of study have been reluctantly obliged to narrow in more and more their range of reading and of effort to keep abreast of the advance in their several departments. Lastly, these twenty-one years have been characterised as the "coming of age" of that great system of philosophy with which the names of three Englishmen—Darwin, Spencer, and Wallace—are associated as its founders. Whatever opinions one may entertain as to the sufficiency and finality of this philosophy, there can be no question as to its influence on scientific thought. On the one hand, it is inaccurate to compare it with so entirely different things as the discovery of the chemical elements and of the law of gravitation; on the other, it is scarcely fair to characterise it as a mere "confused development" of the mind of the age. It is indeed a new attempt of science in its maturer years to grapple with those mysterious questions of origins which occupied it in the days of its infancy, and it is to be hoped that it may not, like the Titans of ancient fable, be hurled back from heaven, or, like the first mother, find the knowledge to which it aspires a bitter thing. In any case we should fully understand the responsibility which we incur when in these times of full-grown science we venture to deal with the great problem of origins, and should be prepared to find that in this field the new philosophy, like those which have preceded it, may meet with very imperfect success. The agitation of these subjects has already brought science into close relations, sometimes friendly, sometimes hostile, it is to be hoped in the end helpful, with those great and awful questions of the ultimate destiny of humanity, and its relations to its Creator, which must always be nearer to the human heart than any of the achievements of science on its own ground. In entering on such questions we should proceed with caution and reverence, feeling that we are on holy ground, and that though, like Moses of old, we may be armed with all the learning of our time, we are in the presence of that which while it burns is not consumed; of a mystery which neither observation, experiment, nor induction can ever fully solve.

In a recent address, the late President of the Royal Society called attention to the fact that, within the life-time of the older men of science of the present day, the greater part of the vast body of knowledge included in the modern sciences of physics, chemistry, biology, and geology has been accumulated, and the most important advances made in its application to such common and familiar things as the railway, ocean navigation, the electric telegraph, electric lighting, the telephone, the germ-theory of disease, the use of anæsthetics, the processes of metallurgy, and the dyeing of fabrics. Even since the last meeting in this city much of this great work has been done, and has led to general results of the most marvellous kind. What at that time could have appeared more chimerical than the opening up, by the enterprise of one British colony, of a shorter road to the East by way of the extreme West, realising what was happily called by Milton and Cheadle "the new North-West Passage," making Japan the next neighbour of Canada on the west, and offering to Britain a new way to her Eastern possessions; or than the possibility of this Association holding a successful meeting on the other side of the Atlantic? We have now an invitation to meet in Australia, and may, if we please, proceed thither by the Canadian Pacific Railway and its new lines of steamers, returning by the Suez Canal.[1] To-day this is quite as feasible as the Canadian visit would have been in 1865. It is science that has thus brought the once widely separated parts of the world nearer to each other, and is breaking down those geographical barriers which have separated the different portions of our widely extended British race. Its work in this is not yet complete. Its goal to-day is its starting-point to-morrow. It is as far as at any previous time from seeing the limit of its conquests, and every victory gained is but the opening of the way for a further advance.

By its visit to Canada the British Association has asserted its Imperial character, and has consolidated the scientific interests of Her Majesty's dominions, in advance of that great gathering of the industrial products of all parts of the Empire now on exhibition in London, and in advance of any political plans of Imperial federation.[1] There has even been a project before us for an International Scientific Convention, in which the great English Republic of America shall take part—a project the realisation of which was to some extent anticipated in the fusion of the members of the British and American Associations at Montreal and Philadelphia in 1884. As a Canadian, as a past President of the American Association, and now honoured with the Presidency of this Association, I may be held to represent in my own person this scientific union of the British Islands, of the various Colonies, and of the great Republic, which, whatever the difficulties attending its formal accomplishment at present, is certain to lead to an actual and real union for scientific work. In furtherance of this I am glad to see here to-day influential representatives of most of the British Colonies, of India, and of the United States. We welcome here also delegates from other countries, and though the barrier of language may at present prevent a larger union, we may entertain the hope that Britain, America, India, and the Colonies, working together in the interest of science, may ultimately render our English tongue the most general vehicle of scientific thought and discovery—a consummation of which I think there are, at present, many indications.

But, while science marches on from victory to victory, its path is marked by the resting-places of those who have fought its battles and assured its advance. In looking back to 1865 there rise before me the once familiar countenances of Phillips, Murchison, Lyell, Forbes, Jeffreys, Jukes, Rolleston, Miller, Spottiswoode, Fairbairn, Gassiot, Carpenter, and a host of others, present in full vigour at that meeting, but no more with us. These were veterans of science; but, alas! many then young and rising in fame are also numbered with the dead. It may be that before another Birmingham meeting many of us, the older members now, will also have passed away. But these men have left behind them ineffaceable monuments of their work, in which they still survive, and we rejoice to believe that, though dead to us, they live in that company of the great and good of all ages who have entered into that unseen Universe where all that is high and holy and beautiful must go on accumulating till the time of the restitution of all things. Let us follow their example and carry on their work, as God may give us power and opportunity, gathering in precious stores of knowledge and of thought, in the belief that all truth is immortal, and must go on for ever bestowing blessings on mankind. Thus will the memory of the mighty dead remain to us as a power which,

"Like a star,
Beacons from the abode where the eternal are."

I do not wish, however, to occupy your time longer with general or personal matters, but rather to take the opportunity afforded by this address to invite your attention to some topics of scientific interest. In attempting to do this, I must have before me the warning conveyed by Prof. Huxley, in the address to which I have already referred, that in our time science, like Tarpeia, may be crushed with the weight of the rewards bestowed on her. In other words, it is impossible for any man to keep pace with the progress of more than one limited branch of science, and it is equally impossible to find an audience of scientific men of whom anything more than a mere fraction can be expected to take an interest in any one subject. There is, however, some consolation in the knowledge that a speaker who is sufficiently simple for those who are advanced specialists in other departments, will of necessity be also sufficiently simple to be understood by the general public who are specialists in nothing. On this principle a geologist of the old school, accustomed to a great variety of work, may hope so to scatter his fire as to reach the greater part of the audience. In endeavouring to secure this end, I have sought inspiration from that ocean which connects rather than separates Britain and America, and may almost be said to be an English sea—the North Atlantic. The geological history of this depression of the earth's crust, and its relation to the continental masses which limit it, may furnish a theme at once generally intelligible and connected with great questions as to the structure and history of the earth, which have excited the attention alike of physicists, geologists, biologists, geographers, and ethnologists. Should I, in treating of these questions, appear to be somewhat abrupt and dogmatic, and to indicate rather than state the

[1] It is expected that, on the completion of the whole of the connections of the Canadian Pacific Railway, the time from ocean to ocean may be reduced to 116 hours, and from London to Hong Kong to 27 days.

[1] I should note here, in connection with this, the valuable volume of "Canadian Economics," edited by Mr. D. A. P. Watt, which was one of the results of the Montreal meeting.

evidence of the general views announced, I trust you will kindly attribute this to the exigencies of a short address.

If we imagine an observer contemplating the earth from a convenient distance in space, and scrutinising its features as it rolls before him, we may suppose him to be struck with the fact that eleven-sixteenths of its surface are covered with water, and that the land is so unequally distributed that from one point of view he would see a hemisphere almost exclusively oceanic, while nearly the whole of the dry land is gathered in the opposite hemisphere. He might observe that the great oceanic area of the Pacific and Antarctic Oceans is dotted with islands—like a shallow pool with stones rising above its surface—as if its general depth were small in comparison with its area. He might also notice that a mass or belt of land surrounds each Pole, and that the northern ring sends off to the southward three vast tongues of land and of mountain-chains, terminating respectively in South America, South Africa, and Australia, towards which feebler and insular processes are given off by the Antarctic continental mass. This, as some geographers have observed,[1] gives a rudely three-ribbed aspect to the earth, though two of the three ribs are crowded together and form the Europ-asian mass, or double continent, while the third is isolated in the single continent of America. He might also observe that the northern girdle is cut across, so that the Atlantic opens by a wide space into the Arctic Sea, while the Pacific is contracted towards the north, but confluent with the Antarctic Ocean. The Atlantic is also relatively deeper and less cumbered with islands than the Pacific, which has the higher ridges near its shores, constituting what some visitors to the Pacific coast of America have not inaptly called the "back of the world," while the wider slopes face the narrower ocean, into which for this reason the greater part of the drainage of the land is poured.[2] The Pacific and Atlantic, though both depressions or flattenings of the earth, are, as we shall find, different in age, character, and conditions; and the Atlantic, though the smaller, is the older, and, from the geological point of view, in some respects the more important of the two.

If our imaginary observer had the means of knowing anything of the rock-formations of the continents, he would notice that those bounding the North Atlantic are in general of great age, some belonging to the Laurentian system. On the other hand, he would see that many of the mountain-ranges along the Pacific are comparatively new, and that modern igneous action occurs in connection with them. Thus he might be led to believe that the Atlantic, though comparatively narrow, is an older feature of the earth's surface, while the Pacific belongs to more modern times. But he would note in connection with this that the oldest rocks of the great continental masses are mostly toward their northern ends, and that the borders of the northern ring of land and certain ridges extending southwards from it constitute the most ancient and permanent elevations of the earth's crust, though now greatly surpassed by mountains of more recent age nearer the equator. Before leaving this general survey we may make one further remark. An observer looking at the earth from without would notice that the margins of the Atlantic and the main lines of direction of its mountain-chains are north-east and south-west, and north-west and south-east, as if some early causes had determined the occurrence of elevations along great circles of the earth's surface tangent to the polar circles.

We are invited by the preceding general glance at the surface of the earth to ask certain questions respecting the Atlantic:—(1) What has at first determined its position and form? (2) What changes has it experienced in the lapse of geological time? (3) What relations have these changes borne to the development of life on the land and in the water? (4) What is its probable future?

Before attempting to answer these questions, which I shall not take up formally in succession, but rather in connection with each other, it is necessary to state as briefly as possible certain general conclusions respecting the interior of the earth. It is popularly supposed that we know nothing of this beyond a superficial crust perhaps averaging 50,000 to 100,000 feet in thickness. It is true we have no means of exploration in the earth's interior, but the conjoined labours of physicists and geologists have now proceeded sufficiently far to throw much inferential light on the subject, and to enable us to make some general affirmations with certainty; and these it is the more necessary to state distinctly, since they are often treated as mere subjects of speculation and fruitless discussion.

(1) Since the dawn of geological science it has been evident that the crust on which we live must be supported on a plastic or partially liquid mass of heated rock, approximately uniform in quality under the whole of its area. This is a legitimate conclusion from the wide distribution of volcanic phenomena, and from the fact that the ejections of volcanoes, while locally of various kinds, are similar in every part of the world. It led to the old idea of a fluid interior of the earth, but this is now generally abandoned, and this interior heated and plastic layer is regarded as merely an under-crust.

(2) We have reason to believe, as the result of astronomical investigations,[1] that, notwithstanding the plasticity or liquidity of the under-crust, the mass of the earth—its nucleus as we may call it—is practically solid and of great density and hardness. Thus we have the apparent paradox of a solid yet fluid earth, solid in its astronomical relations, liquid or plastic for the purposes of volcanic action and superficial movements.[2]

(3) The plastic sub-crust is not in a state of dry igneous fusion, but in that condition of aqueo-igneous or hydro-thermic fusion which arises from the action of heat on moist substances, and which may either be regarded as a fusion or as a species of solution at a very high temperature. This we learn from the phenomena of volcanic action, and from the composition of the volcanic and plutonic rocks, as well as from such chemical experiments as those of Daubrée and of Tilden and Shenstone.[3]

(4) The interior sub-crust is not perfectly homogeneous, but may be roughly divided into two layers or magmas, as they have been called: an upper, highly siliceous or acidic, of low specific gravity and light-coloured, and corresponding to such kinds of plutonic and volcanic rocks as granite and trachyte; and a lower, less siliceous or more basic, more dense, and more highly charged with iron, and corresponding to such igneous rocks as the dolerites, basalts, and kindred lavas. It is interesting here to note that this conclusion, elaborated by Durocher and Von Waltershausen, and usually connected with their names, appears to have been first announced by John Phillips, in his "Geological Manual," and as a mere common-sense deduction from the observed phenomena of volcanic action and the probable results of the gradual cooling of the earth.[4] It receives striking confirmation from the observed succession of acidic and basic volcanic rocks of all geological periods and in all localities. It would even seem, from recent spectroscopic investigations of Lockyer, that there is evidence of a similar succession of magmas in the heavenly bodies, and the discovery by Nordenskjöld of native iron in Greenland basalts affords a probability that the inner magma is in part metallic.[5]

(5) Where rents or fissures form in the upper crust, the material of the lower crust is forced upward by the pressure of the less supported portions of the former, giving rise to volcanic phenomena either of an explosive or quiet character, as may be determined by contact with water. The underlying material

[1] Dana, "Manual of Geology," introductory part. Green, "Vestiges of a Molten Globe," has summed up these facts.

[2] Mr. Mellard Reade, in two Presidential addresses before the Geological Society of Liverpool, has well illustrated this point and its geological consequence.

[1] Hopkins, Mallet, Sir William Thomson, and Prof G. H. Darwin maintain the solidity and rigidity of the earth on astronomical grounds; but different conclusions have been reached by Hennesey, Delaunay, and Airy. In America, Barnard and Crosby, Dutton, Le Conte, and Wadsworth have discussed these questions.

[2] An objection has been taken to the effect that the supposed ellipsoidal form of the equator is inconsistent with a plastic sub-crust. But this ellipsoidal form is not absolutely certain, or, if it exists, is very minute. Bonney has in a recent lecture suggested the important consideration that a mass may be slowly mobile under long-continued pressure, while yet rigid with reference to more sudden movements.

[3] *Phil. Trans.*, 1884. Also Crosby in *Proc. Boston Soc. Nat. Hist.*, 1883.

[4] Phillips says ("Manual of Geology," 1855, p. 493):—"If we regard them (the internal crystalline rocks) as acquiring solidification by cooling in zones parallel to the surface, we should have sheets of granitic and basaltic rocks generated below, the first uppermost, the last undermost, while above the several strata were produced in a series beginning at the bottom. In this sense the rocks of fusion may be called, with Lyell, *hypogene*. Certainly under particular areas of country are found evidence of the liquefaction of one set of igneous products after the solidification of others. Many dykes of basalt traversing granite show themselves to have been in fusion after the solidification of the granite." In various forms Phillips returns to this idea, as at pp. 556 and 564, in that unpretending manner which was his wont. Dr. Sterry Hunt has kindly directed my attention to the fact of Phillips's right of priority in this matter. Durocher in 1857 elaborated the theory of magmas in the *Annales des Mines*, and we are indebted to Dutton, of the United States Geological Survey, for its detailed application to the remarkable volcanic outflows of Western America.

[5] These basalts occur at Ovifak, Greenland. Andrews has found small particles of iron in British basalts. Prestwich and Judd have referred to the bearing on general geology of these facts, and of Lockyer's suggestions.

may also be carried to the surface by the agency of heated water, producing those quiet discharges which Hunt has named crenitic. It is to be observed here that explosive volcanic phenomena, and the formation of cones, are, as Prestwich has well remarked, characteristic of an old and thickened crust; quiet ejection from fissures and hydro-thermal action may have been more common in earlier periods and with a thinner over-crust.

(6) The contraction of the earth's interior by cooling and by the emission of material from below the over-crust, has caused this crust to press downward, and therefore laterally, and so to effect great bends, folds, and plications; and these modified subsequently by surface denudation constitute mountain-chains and continental plateaus. As Hall long ago pointed out,[1] such lines of folding have been produced more especially where thick sediments had been laid down on the sea-bottom. Thus we have here another apparent paradox, namely, that the elevations of the earth's crust occur in the places where the greatest burden of detritus has been laid down upon it, and where consequently the crust has been softened and depressed. We must beware, in this connection, of exaggerated notions of the extent of contraction and of crumbling required to form mountains. Bonney has well shown, in lectures delivered at the London Institution, that an amount of contraction, almost inappreciable in comparison with the diameter of the earth, would be sufficient; and that as the greatest mountain-chains are less than 1/600 of the earth's radius in height, they would on an artificial globe a foot in diameter be no more important than the slight inequalities that might result from the paper gores overlapping each other at the edges.

(7) The crushing and sliding of the over-crust inplied in these movements raise some serious questions of a physical character. One of these relates to the rapidity or slowness of such movements, and the consequent degree of intensity of the heat developed, as a possible cause of metamorphism of rocks. Another has reference to the possibility of changes in the equilibrium of the earth itself as resulting from local collapse and ridging. These questions in connection with the present dissociation of the axis of rotation from the magnetic poles, and with changes of climate, have attracted some attention,[2] and probably deserve further consideration on the part of physicists. In so far as geological evidence is concerned, it would seem that the general association of crumbling with metamorphism indicates a certain rapidity in the process of mountain-making, and consequent development of heat, and the arrangement of the older rocks around the Arctic basin forbids us from assuming any extensive movement of the axis of rotation, though it does not exclude changes to a limited extent. I hope that Prof. Darwin will discuss these points in his address to the Physical Section.

I wish to formulate these principles as distinctly as possible, and as the result of all the long series of observations, calculations, and discussions since the time of Werner and Hutton, and in which a vast number of able physicists and naturalists have borne a part, because they may be considered as certain deductions from our actual knowledge, and because they lie at the foundation of a rational physical geology.

We may popularise these deductions by comparing the earth to a drupe or stone-fruit, such as a plum or peach, somewhat dried up. It has a large and intensely hard stone and kernel, a thin pulp made up of two layers, an inner more dense and dark-coloured, and an outer less dense and lighter-coloured. These constitute the under-crust. On the outside it has a thin membrane or over-crust. In the process of drying it has slightly shrunk, so as to produce ridges and hollows of the outer crust, and this outer crust has cracked in some places, allowing portions of the pulp to ooze out—in some of these its lower dark substance, in others its upper and lighter material. The analogy extends no further, for there is nothing in our withered fruit to represent the oceans occupying the lower parts of the surface or the deposits which they have laid down.

Keeping in view these general conclusions, let us now turn to their bearing on the origin and history of the North Atlantic.

Though the Atlantic is a deep ocean, its basin does not constitute so much a depression of the crust of the earth as a flattening of it, and this, as recent soundings have shown, with a slight ridge or elevation along its middle, and banks or terraces fringing the edges, so that its form is not so much that of a basin as that of a shallow plate with its middle a little raised. Its true permanent margins are composed of portions of the over-crust folded, ridged up, and crushed, as if by lateral pressure emanating from the sea itself. We cannot, for example, look at a geological map of America without perceiving that the Appalachian ridges, which intervene between the Atlantic and the St. Lawrence Valley, have been driven bodily back by a force acting from the east, and that they have resisted this pressure only where, as in the Gulf of St. Lawrence and the Catskill region of New York, they have been protected by outlying masses of very old rocks, as, for example, by that of the Island of Newfoundland and that of the Adirondack Mountains. The admirable work begun by my friend and fellow-student, Prof. James Nicol, followed up by Hicks, Lapworth, and others, and now, after long controversy, fully confirmed by the recent observations of the Geological Survey of Scotland, has shown the most intense action of the same kind on the east side of the ocean in the Scottish highlands; and the more widely distributed Eozoic rocks of Scandinavia may be appealed to in further evidence of this.[1]

If we now inquire as to the cause of the Atlantic depression, we must go back to a time when the areas occupied by the Atlantic and its bounding coasts were parts of a shoreless sea in which the earliest gneisses or stratified granites of the Laurentian age were being laid down in vastly extended beds. These ancient crystalline rocks have been the subject of much discussion and controversy, and as they constitute the lowest and probably the firmest part of the Atlantic sea-bed, it is necessary to inquire as to their origin and history. Dr. Bonney, the late President of the Geological Society, in his anniversary address, and Dr. Sterry Hunt, in an elaborate paper communicated to the Royal Society of Canada, have ably summed up the hypotheses as to the origin of the oldest Laurentian beds. At the basis of these hypotheses lies the admission that the immensely thick beds of orthoclase gneiss, which are the oldest stratified rocks known to us, are substantially the same in composition with the upper or siliceous magma or layer of the under-crust. They are, in short, its materials either in their primitive condition or merely re-arranged. One theory considers them as original products of cooling, owing their lamination merely to the successive stages of the process. Another view refers them to the waste and re-arrangement of the materials of a previously massive granite. Still another holds that all our granites really arise from the fusion of old gneisses of originally aqueous origin; while a fourth refers the gneisses themselves to molecular changes effected in granite by pressure. These several views, in so far as they relate to the oldest or fundamental Laurentian gneiss, may be arranged under the following heads:—(1) *Endoplutonic*, or that which regards all the old gneisses as molten rocks cooled from without inward in successive layers.[2] (2) *Exoplutonic*, or that which considers them as made up of matter ejected from below the upper crust in the manner of volcanic action.[3] (3) *Metamorphic*, which supposes the old gneisses to arise from the crystallisation of detrital matter spread over the sea-bottom, and either igneous or derived from the decay of igneous rocks.[4] (4) *Chaotic* or *Thermo-chaotic*, or the theory of deposit from the turbid waters of a primæval ocean either with or without the aid of heat.[5] In one form this was the old theory of Werner. (5) *Crenitic* or *Hydro-thermic*, which supposes the action of heated waters penetrating below the crust to be constantly bringing up to the surface mineral matters in solution and depositing these so as to form feldspathic and other rocks.[6]

[6] Hunt, *loc. cit.* The following is Dr. Hunt's summary statement of this theory:—"The globe consolidating at the centre left, it is conceived, a superficial layer of basic silicates, which has yielded all the fixed elements of the earth's crust. This layer formed the first land and the floor of the primæval sea, the acid waters of which, permeating and partially decomposing it, became thereby chemically neutralised. This last-cooled layer, mechanically disintegrated, saturated with water, and heated by the central mass, was the source of mineral springs, holding in solution the silicates which built up the ancient gneisses and similar rocks. Granitic veins and zeolites are due to survivals of the process which generated the gneissic rocks. The hypothesis of their formation from materials brought to the surface by mineral springs from the primitive basic layer affords, it is claimed, the elements of a complete and intelligible explanation of the origin of the Eozoic rocks. This upward lixiviation of the primitive mass, and the deposition over it of an acidic granite-like rock, would leave below a highly basic material, and the division of the mass thus established would correspond to that of the trachytic

It will be observed, in regard to these theories, that none of them supposes that the old gneiss is an ordinary sediment, but that all regard it as formed in exceptional circumstances, these circumstances being the absence of land and of sub-aërial decay of rock, and the presence wholly or principally of the material of the upper surface of the recently hardened crust. This being granted, the question arises, Ought we not to combine these several theories and to believe that the cooling crust has hardened in successive layers from without inward; that at the same time fissures were locally discharging igneous matter to the surface; that matter held in suspension in the ocean, and matter held in solution by heated waters rising from beneath the outer crust were mingling their materials in the deposits of the primitive ocean? It would seem that the combination of all these agencies may safely be invoked as causes of the pre-Atlantic deposits. This is the eclectic position which I endeavoured to maintain in my address before the Minneapolis meeting of the American Association in 1883, and which I still hold to be in every way probable.

A word here as to metamorphism, a theory which, like many others, has been first run to death and then discredited, but which to the moderate degree in which it was originally held by Lyell is still valid. Nothing can be more certain than that the composition of the Laurentian gneisses forbids us to suppose that they can be ordinary sediments metamorphosed. They are rocks peculiar in their origin, and not paralleled unless exceptionally in later times. On the other hand, they have undoubtedly experienced very important changes, more especially as to crystallisation, the state of combination of their ingredients, and the development of disseminated minerals;[1] and while this may in part be attributed to the mechanical pressure to which they have been subjected, it requires also the action of hydrothermic agencies. Any theory which fails to invoke both of these kinds of force must necessarily be partial and imperfect.

But all metamorphic rocks are not of the same character with the gneisses of the Lower Laurentian. Even in the Middle and Upper Laurentian we have metamorphic rocks, *e.g.* quartzite and limestone, which must originally have been ordinary aqueous deposits. Still more in the succeeding Huronian and its associated series of beds, and in the Lower Palæozoic, local metamorphic change has been undergone by rocks quite similar to those which in their unaltered state constitute regular sedimentary deposits. In the case of these later rocks it is to be borne in mind that, while some may have been of volcanic origin, others may have been sediments rich in undecomposed fragments of silicates. It is a mistake to suppose that the ordinary decay of stratified siliceous rocks is a process of kaolinisation so perfect as to eliminate all alkaline matters. On the contrary, the fact, which Judd has recently well illustrated in the case of the mud of the Nile, applies to a great number of similar deposits in all parts of the world, and shows that the finest sediments have not usually been so completely lixiviated as to be destitute of the basic matters necessary for their conversion into gneiss, mica-schist, and similar rocks when the necessary agencies of metamorphism are applied to them, and this quite independently of any extraneous matters introduced into them by water or otherwise. Still it must be steadily kept in view that many of the old pre-Cambrian crystalline rocks must have been different originally from those succeeding them, and that consequently these last even when metamorphosed present different characters.

I may remark here that, though a palæontologist rather than a lithologist, it gives me great pleasure to find so much attention now given in this country to the old crystalline rocks, and to their study microscopically and chemically as well as in the field, a work in which Sorby and Allport were pioneers. As a pupil of the late Prof. Jameson, of Edinburgh, my own attention was early attracted to the study of minerals and rocks as the stable foundations of geological science; and as far back as 1841 I had learnt of the late Mr. Sanderson, of Edinburgh, who worked at Nicol's sections, how to slice rocks and fossils; and since that time I have been in the habit of examining everything with the microscope. The modern developments in this direction are therefore very gratifying, even though, as is natural, they may sometimes appear to be pushed too far or their value over-estimated.

That these old gneisses were deposited not only in what is now the bed of the Atlantic, but also on the great continental areas of America and Europe, any one who considers the wide extent of these rocks represented on the map recently published by Prof. Hull can readily understand (*Trans.* Royal Irish Academy). It is true that Hull supposes that the basin of the Atlantic itself may have been land at this time, but there is no evidence of this, more especially as the material of the gneiss could not have been detritus derived from sub-aërial decay of rock.

Let us suppose, then, the floor of old Ocean covered with a flat pavement of gneiss, or of that material which is now gneiss, the next question is, How and when did this original bed become converted into sea and land? Here we have some things certain, others most debatable. That the cooling mass, especially if it was sending out volumes of softened rocky material, either in the exoplutonic or in the crenitic way, and piling this on the surface, must soon become too small for its shell, is apparent; but when and where would the collapse, crushing, and wrinkling inevitable from this cause begin? Where they did begin is indicated by the lines of mountain-chains which traverse the Laurentian districts; but the reason why is less apparent. The more or less unequal cooling, hardening, and conductive power of the outer crust we may readily assume. The driftage unequally of water-borne detritus to the south-west by the bottom currents of the sea is another cause, and, as we shall soon see, most effective. Still another is the greater cooling and hardening of the crust in the polar regions, and the tendency to collapse of the equatorial protuberance from the slackening of the earth's rotation. Besides these the internal tides of the earth's substance at the times of solstice would exert an oblique pulling force on the crust, which might tend to crack it along diagonal lines. From whichever of these causes or the combination of the whole, we know that within the Laurentian time folded portions of the earth's crust began to rise above the general surface in broad belts running from north-east to south-west, and from north-west to south-east, where the older mountains of Eastern America and Western Europe now stand, and that the subsidence of the oceanic areas allowed by this crumpling of the crust permitted other areas on both sides of what is now the Atlantic to form limited table-lands.[1] This was the beginning of a process repeated again and again in subsequent times, and which began in the Middle Laurentian, when for the first time we find beds of quartzite, limestone, and iron ore, and graphitic beds, indicating that there was already land and water, and that the sea, and perhaps the land, swarmed with animal and plant life of forms unknown to us for the most part now. Independently of the questions as to the animal nature of Eozoon, I hold that we know, as certainly as we can know anything inferentially, of the existence of these primitive forms of life. If I were to conjecture what were the early forms of plant and animal life, I would suppose that just as in the Palæozoic the acrogens culminated in gigantic and complex forest trees, so in the Laurentian the Algæ, the lichens, and the mosses grew to dimensions and assumed complexity of structure unexampled in later times, and that in the sea the humbler forms of Protozoa and Hydrozoa were the dominant types, but in gigantic and complex forms. The land of this period was probably limited, for the most part, to high latitudes, and its aspect, though more rugged and abrupt, and of greater elevation, must have been of that character which we still see in the Laurentian hills. The distribution of this ancient land is indicated by the long lines of old Laurentian rock extending from the Labrador coast and the north shore of the St. Lawrence, and along the eastern slopes of the Appalachians in America, and the like rocks of the Hebrides, the Western Highlands, and the Scandinavian mountains. A small but interesting remnant is that in the Malvern Hills, so well described by Holl. It will be well to note here, and to fix on our minds, that these ancient ridges of Eastern America and Western Europe have been greatly denuded and wasted since Laurentian times, and that it is along their eastern sides that the greatest sedimentary accumulations have been deposited.

From this time dates the introduction of that dominance of

and doleritic magmas, which have been conjectured to be the sources of two great types of eruptive rocks. Inasmuch, however, as according to the present hypothesis these two layers of basic and acidic matters are the results of aqueous action, and not of an original separation in a plutonic mass, as imagined by Phillips and Durocher, their composition would be subject to many local variations."

[1] The first of these is what Bonney has called *Metastasis*. The second and third come under the name *Metacrasis*. *Methylosis*, or change of substance, is altogether exceptional, and not to be credited except on the best evidence, or in cases where volatile matters have been expelled, as in the change of hæmatite into magnetite, or of bituminous coal into anthracite.

[1] Daubrée's curious experiments on the contraction of caoutchouc balloons partially hardened by coating with varnish, shows how small inequalities of the crust, from whatever cause arising, might affect the formation of wrinkles, and also that transverse as well as longitudinal wrinkling might occur.

existing causes which forms the basis of uniformitarianism in geology, and which had to go on with various and great modifications of detail, through the successive stages of the geological history, till the land and water of the northern hemisphere attained to their present complex structure.

So soon as we have a circumpolar belt or patches of Eozoic (or Archæan, or pre-Cambrian, if these terms are preferred) land, and ridges running southward from it, we enter on new and more complicated methods of growth of the continents and seas. Here we are indebted to Le Conte for clearly pointing out that our original Eozoic tracts of continent were in the earliest times areas of deposition, and that the first elevations of land out of the primæval ocean must have differed in important points from all that have succeeded them; but they were equally amenable to the ordinary laws of denudation. Portions of these oldest crystalline rocks, raised out of the protecting water, were now eroded by atmospheric agents, and especially by the carbonic acid, then existing in the atmosphere perhaps more abundantly than at present, under whose influence the hardest of the gneissic rocks gradually decay. The Arctic lands were subjected in addition to the powerful mechanical force of frost and thaw. Thus every shower of rain and every swollen stream would carry into the sea the products of the waste of land, sorting them into fine clays and coarser sands; and the cold currents which cling to the ocean bottom, now determined in their courses, not merely by the earth's rotation, but also by the lines of folding on both sides of the Atlantic, would carry south-westward, and pile up in marginal banks of great thickness, the debris produced from the rapid waste of the land already existing in the Arctic regions. The Atlantic, opening widely to the north, and having large rivers pouring into it, was especially the ocean characterised, as time advanced, by the prevalence of these phenomena. Thus throughout the geological history it has happened that, while the middle of the Atlantic has received merely organic deposits of shells of Foraminifera and similar organisms, and this probably only to a small amount, its margins have had piled upon them beds of detritus of immense thickness. Prof. Hall, of Albany, was the first geologist who pointed out the vast cosmic importance of these deposits, and that the mountains of both sides of the Atlantic owe their origin to these great lines of deposition, along with the fact, afterwards more fully insisted on by Rogers, that the portions of the crust which received these masses of debris became thereby weighted down and softened, and were more liable than other parts to lateral crushing.[1]

Thus in the later Eozoic and early Palæozoic times, which succeeded the first foldings of the oldest Laurentian, great ridges were thrown up, along the edges of which were beds of limestone, and on their summits and sides thick masses of ejected igneous rocks. In the bed of the central Atlantic there are no such accumulations. It must have been a flat, or slightly ridged, plate of the ancient gneiss, hard and resisting, though perhaps with a few cracks, through which igneous matter welled up, as in Iceland and the Azores in more modern times. In this condition of things we have causes tending to perpetuate and extend the distinctions of ocean and continent, mountain and plain, already begun; and of these we may more especially note the continued subsidence of the areas of greatest marine deposition. This has long attracted attention, and affords very convincing evidence of the connection of sedimentary deposit as a cause with the subsidence of the crust.[2]

We are indebted to a French physicist, M. Faye (*Revue Scientifique*, 1886), for an important suggestion on this subject. It is that the sediment accumulated along the shores of the ocean presented an obstacle to radiation, and consequently to cooling of the crust, while the ocean floor, unprotected and unweighted, and constantly bathed with currents of cold water, having great power of convection of heat, would be more rapidly cooled, and so would become thicker and stronger. This suggestion is complementary to the theory of Prof. Hall, that the areas of greatest deposit on the margins of the ocean are necessarily those of greatest folding and consequent elevation. We have thus a hard thick resisting ocean bottom which, as it settles down toward the interior, under the influence of gravity, squeezes upward and folds and plicates all the soft sediments deposited on its edges. The Atlantic area is almost an unbroken cake of this kind. The Pacific area has cracked in many places, allowing the interior fluid matter to ooze out in volcanic ejections.

It may be said that all this supposes a permanent continuance of the ocean basins, whereas many geologists postulate a mid-Atlantic continent[1] to give the thick masses of detritus found in the older formations both in Eastern America and Western Europe, and which thin off in proceeding into the interior of both continents. I prefer with Hall to consider these belts of sediment as in the main the deposits of northern currents, and derived from Arctic land, and that like the great banks of the American coast at the present day, which are being built up by the present Arctic current, they had little to do with any direct drainage from the adjacent shore. We need not deny, however, that such ridges of land as existed along the Atlantic margins were contributing their quota of river-borne material, just as on a still greater scale the Amazon and Mississippi are doing now, and this especially on the sides toward the present continental plateaus, though the greater part must have been derived from the wide tracts of Laurentian land within the Arctic Circle or near to it. It is further obvious that the ordinary reasoning respecting the necessity of continental areas in the present ocean basins would actually oblige us to suppose that the whole of the oceans and continents had repeatedly changed places. This consideration opposes enormous physical difficulties to any theory of alternations of the oceanic and continental areas, except locally at their margins. I would, however, refer you for a more full discussion of these points to the address to be delivered to-morrow by the President of the Geological Section.

But the permanence of the Atlantic depression does not exclude the idea of successive submergences of the continental plateaus and marginal slopes, alternating with periods of elevation, when the ocean retreated from the continents and contracted its limits. In this respect the Atlantic of to-day is much smaller than it was in those times when it spread widely over the continental plains and slopes, and much larger than it has been in times of continental elevation. This leads us to the further consideration that, while the ocean beds have been sinking, other areas have been better supported, and constitute the continental plateaus; and that it has been at or near the junctions of these sinking and rising areas that the thickest deposits of detritus, the most extensive foldings, and the greatest ejections of volcanic matter have occurred. There has thus been a permanence of the position of the continents and oceans throughout geological time, but with many oscillations of these areas, producing submergences and emergences of the land. In this way we can reconcile the vast vicissitudes of the continental areas in different geological periods with that continuity of development from north to south, and from the interiors to the margins, which is so marked a feature. We have for this reason to formulate another apparent geological paradox, namely, that while in one sense the continental and oceanic areas are permanent, in another they have been in continual movement. Nor does this view exclude extension of the continental borders or of chains of islands beyond their present limits, at certain periods; and indeed the general principle already stated, that subsidence of the ocean bed has produced elevation of the land, implies in earlier periods a shallower ocean and many possibilities as to volcanic islands, and low continental margins creeping out into

[1] The connection of accumulation with subsidence was always a familiar consideration with geologists; but Hall seems to have been the first to state its true significance as a geological factor, and to see that those portions of the crust which are weighted down by great detrital accumulations are necessarily those which, in succeeding movements, were elevated into mountains. Other American geologists, as Dana, Rogers, Hunt, Le Conte, Crosby, &c., have followed up Hall's primary suggestion, and in England, Hicks, Fisher, Starkie Gardner, Hull, and others, have brought it under notice, and it enters into the great generalisations of Lyell on these subjects.

[2] Dutton in "Report of U S. Geological Survey," 1881. From facts stated in this report and in my "Acadian Geology," it is apparent that in the Western States and in the coal-field of Nova Scotia shallow-water deposits have been laid down up to thicknesses of 10,000 to 20,000 feet in connection with continuous subsidence. See also a paper by Ricketts in the *Geol. Mag.* 1883. It may be well to add here that this doctrine of the subsidence of wide areas being caused by deposition does not justify the conclusion of certain glacialists that snow and ice have exercised a like power in glacial periods. In truth, as will appear in the sequel, great accumulations of snow and ice require to be preceded by subsidence, and wide continental areas can never be covered with deep snow, while of course ice can cause no addition of weight to submerged areas.

[1] Among American geologists, Dana and Le Conte, though from somewhat different premises, maintain continental permanence. Crosby has argued on the other side. In Britain, Hull has elaborated the idea of interchange of oceanic and continental areas in his memoir in *Trans.* Dublin Society, and in his work entitled "The Physical History of the British Islands." Godwin-Austen argues powerfully for the permanence of the Atlantic basin, *Q. J. Geol. Soc.* vol. xii. p. 42. Mellard Reade ably advocates the theory of mutation. The two views require, in my judgment, to be combined. More especially it is necessary to take into the account the existence of an Atlantic ridge of Laurentian rock on the west side of Europe, of which the Hebrides and the oldest rocks of Wales, Ireland, Western France, and Portugal are remnants.

the sea; while it is also to be noted that there are, as already stated, bordering shelves, constituting shallows in the ocean, which at certain periods have emerged as land.

We are thus compelled to believe in the contemporaneous existence in all geological periods, except perhaps the earliest of them, of three distinct conditions of areas on the surface of the earth. (1) Oceanic areas of deep sea, which always continued to occupy in whole or in part the bed of the present ocean. (2) Continental plateaus and marginal shelves, existing as low flats or higher table-lands liable to periodical submergence and emergence. (3) Lines of plication and folding, more especially along the borders of the oceans, forming elevated portions of land, rarely altogether submerged, and constantly affording the material of sedimentary accumulations, while they were also the seats of powerful volcanic ejections.

In the successive geological periods the continental plateaus when submerged, owing to their vast extent of warm and shallow sea, have been the great theatres of the development of marine life and of the deposition of organic limestones, and when elevated they have furnished the abodes of the noblest land faunas and floras. The mountain belts, especially in the north, have been the refuge and stronghold of land life in periods of submergence, and the deep ocean basins have been the perennial abodes of pelagic and abyssal creatures, and the refuge of multitudes of other marine animals and plants in times of continental elevation. These general facts are full of importance with reference to the question of the succession of formations and of life in the geological history of the earth.

So much time has been occupied with these general views that it would be impossible to trace the history of the Atlantic in detail through the ages of the Palæozoic, Mesozoic, and Tertiary. We may, however, shortly glance at the changes of the three kinds of surface already referred to. The bed of the ocean seems to have remained on the whole abyssal, but there were probably periods when those shallow reaches of the Atlantic which stretch across its most northern portion, and partly separate it from the Arctic basin, presented connecting coasts or continuous chains of islands sufficient to permit animals and plants to pass over.[1] At certain periods also there were not unlikely groups of volcanic islands, like the Azores, in the temperate or tropical Atlantic. More especially might this be the case in that early time when it was more like the present Pacific; and the line of the great volcanic belt of the Mediterranean, the mid-Atlantic banks, the Azores, and the West India Islands point to the possibility of such partial connections. These were stepping stones, so to speak, over which land organisms might cross, and some of these may be connected with the fabulous or prehistoric Atlantis.[2]

In the Cambrian and Ordovician periods the distinctions, already referred to, into continental plateaus, mountain-ridges, and ocean depths were first developed, and we find already great masses of sediment accumulating on the seaward sides of the old Laurentian ridges, and internal deposits thinning away from these ridges over the submerged continental areas, and presenting very dissimilar conditions of sedimentation. It would seem also that, as Hicks has argued for Europe, and Logan and Hall for America, this Cambrian age was one of slow subsidence of the land previously elevated, accompanied with or caused by thick deposits of detritus along the borders of the subsiding land, which was probably covered with the decomposing rock arising from long ages of sub-aërial waste.

In the coal-formation age, its characteristic swampy flats stretched in some places far into the shallower parts of the ocean.[3] In the Jurassic the American continent probably extended further to sea than at present. In the Wealden age there was much land to the west and north of Great Britain, and Prof. Bonney has directed attention to the evidence of the existence of this land as far back as the Trias, while Mr. Starkie Gardner has insisted on connecting-links to the southward, as evidenced by fossil plants. So late as the post-Glacial, or early human period, large tracts now submerged formed portions of the continents. On the other hand, the internal plains of America and Europe were often submerged. Such submergences are indicated by the great limestones of the Palæozoic, by the chalk and its representative beds in the Cretaceous, by the Nummulitic formation in the Eocene, and lastly by the great Pleistocene submergence, one of the most remarkable of all, one in which nearly the whole northern hemisphere participated, and which was probably separated from the present time by only a few thousands of years.[1] These submergences and elevations were not always alike on the two sides of the Atlantic. The Salina period of the Silurian, for example, and the Jurassic, show continental elevation in America not shared by Europe. The great subsidences of the Cretaceous and the Eocene were proportionally deeper and wider on the eastern continent, and this and the direction of the land being from north to south cause more ancient forms of life to survive in America. These elevations and submergences of the plateaus alternated with the periods of mountain-making plication, which was going on at intervals at the close of the Eozoic, at the beginning of the Cambrian, at the close of the Siluro-Cambrian, in the Permian, and in Europe and Western America in the Tertiary. The series of changes, however, affecting all these areas was of a highly complex character, and embraces the whole physical history of the geological ages.

We may note here that the unconformities caused by these movements and by subsequent denudation constitute what Le Conte has called "lost intervals," and one of the most important of which is supposed to have occurred at the end of the Eozoic. It is to be observed, however, that as every such movement is followed by a gradual subsidence, the seeming loss is caused merely by the overlapping of the successive beds deposited.

We may also note a fact which I have long ago insisted on ("Acadian Geology," 1865), the regular pulsations of the continental areas, giving us alternations in each great system of formations of deep-sea and shallow-water beds, so that the successive groups of formations may be divided into triplets of shallow-water, deep-water, and shallow-water strata, alternating in each period.

In referring to the ocean basins we should bear in mind that there are three of these in the northern hemisphere—the Arctic, the Pacific, and the Atlantic. De Rance has ably summed up the known facts as to Arctic geology, and more recently Dr. G. M. Dawson has prepared for the Royal Society of Canada a *résumé* and map of what is known of the geology of the Arctic basin (meeting of May 1886; the paper is not yet published), in comparison with Canadian geology. From this it appears that this area presents from without inwards a succession of older and newer formations from the Eozoic to the Tertiary, and that its extent must have been greater in former periods than at present, while it must have enjoyed a comparatively warm climate. The relations of its deposits and fossils are closer with those of the Atlantic than with those of the Pacific, as might be anticipated from its wider opening into the former. Blandford has recently remarked on the correspondence of the marginal deposits around the Pacific and Indian Oceans,[2] and Dr. Dawson informs me that this is equally marked in comparison with the west coast of America,[3] but these marginal areas have not yet gained much on the ocean. In the North Atlantic, on the other hand, there is a wide belt of comparatively modern rocks on both sides, more especially toward the south, and on the American side; but while there appears to be a perfect correspondence on both sides of the Atlantic and around the Pacific respect-

[1] It would seem, from Geikie's description of the Faroe Islands, that they may be a remnant of such connecting land, dating from the Cretaceous or Eocene period.

[2] Dr. Wilson has recently argued that the Atlantis of tradition was really America, and Mr. Hyde Clark has associated this idea with the early dominance in Western Europe of the Iberian race, which Dawkins connects with the Neolithic and Bronze Ages of archæology. My own attention has recently been directed, through specimens presented to the McGill College Museum, to the remarkable resemblances in cranial characters, wampum, and other particulars, of the Guanches of the Canaries with aborigines of Eastern America—resemblances which cannot be accidental.

[3] I have shown the evidence of this in the remnants of Carboniferous districts once more extensive on the Atlantic coast of Nova Scotia and Cape Breton ("Acadian Geology").

[1] The recent surveys of the Falls of Niagara coincide with a great many evidences to which I have elsewhere referred in proving that the Pleistocene submergence of America and Europe came to an end not more than ten thousand years ago, and was itself not of very great duration. Thus in Pleistocene times the land must have been submerged and re-elevated in a very rapid manner.

[2] A singular example is the recurrence in New Zealand of Triassic rocks and fossils of types corresponding to those of British Columbia. A curious modern analogy appears in the works of art of the Maoris with those of the Haida Indians of the Queen Charlotte Islands, and both are eminently Pacific in contradistinction to Atlantic.

[3] *Journal* of Geological Society, May 1886. Blandford's statements respecting the mechanical deposits of the close of the Palæozoic in the Pacific area, whether these are glacial or not, would seem to show a correspondence with the Permian conglomerates and earth-movements of the Atlantic area; but since that time the Atlantic has enjoyed comparative repose. The Pacific also seems to have reproduced the conditions of the Carboniferous in the Cretaceous age, and seems to have been less affected by the great changes of the Pleistocene.

ively, there seems to be less parallelism between the deposits and forms of life of the two oceans as compared with each other, and less correspondence in forms of life, especially in modern times. Still in the earlier geological ages, as might have been anticipated from the imperfect development of the continents, the same forms of life characterise the whole ocean from Australia to Arctic America, and indicate a grand unity of Pacific and Atlantic life not equalled in later times,[1] and which speaks of contemporaneity rather than of what has been termed homotaxis.

We may pause here for a moment to notice some of the effects of Atlantic growth on modern geography. It has given us rugged and broken shores composed of old rocks in the north, and newer formations and softer features towards the south. It has given us marginal mountain-ridges and internal plateaus on both sides of the sea. It has produced certain curious and by no means accidental correspondences of the eastern and western sides. Thus the solid basis on which the British Islands stand may be compared with Newfoundland and Labrador, the English Channel with the Gulf of St. Lawrence, the Bay of Biscay with the Bay of Maine, Spain with the projection of the American land at Cape Hatteras, the Mediterranean with the Gulf of Mexico. The special conditions of deposition and plication necessary to these results, and their bearing on the character and productions of the Atlantic basin, would require a volume for their detailed elucidation.

Thus far our discussion has been limited almost entirely to physical causes and effects. If we now turn to the life-history of the Atlantic, we are met at the threshold with the question of climate, not as a thing fixed and immutable, but as changing from age to age in harmony with geographical mutations, and producing long cosmic summers and winters of alternate warmth and refrigeration.

We can scarcely doubt that the close connection of the Atlantic and Arctic Oceans is one factor in those remarkable vicissitudes of climate experienced by the former, and in which the Pacific area has also shared in connection with the Antarctic Sea. No geological facts are indeed at first sight more strange and inexplicable than the changes of climate in the Atlantic area, even in comparatively modern periods. We know that in the early Tertiary perpetual summer reigned as far north as the middle of Greenland, and that in the Pleistocene the Arctic cold advanced, until an almost perennial winter prevailed, half-way to the equator. It is no wonder that nearly every cause available in the heavens and the earth has been invoked to account for these astounding facts.

It will, I hope, meet with the approval of your veteran glaciologist, Dr. Crosskey, if, neglecting most of these theoretical views, I venture to invite your attention in connection with this question chiefly to the old Lyellian doctrine of the modification of climate by geographical changes. Let us, at least, consider how much these are able to account for.[2]

The ocean is a great equaliser of extremes of temperature. It does this by its great capacity for heat and by its cooling and heating power when passing from the solid into the liquid and gaseous states, and the reverse. It also acts by its mobility, its currents serving to convey heat to great distances, or to cool the air by the movement of cold icy waters. The land, on the other hand, cools or warms rapidly, and can transmit its influence to a distance only by the winds, and the influence so transmitted is rather in the nature of a disturbing than of an equalising cause. It follows that any change in the distribution of land and water must affect climate, more especially if it changes the character or course of the ocean currents.[3]

[1] Daintree and Etheridge, "Queensland Geology," *Journal* of Geological Society, August 1872; R. Etheridge, Junior, "Australian Fossils," *Trans. Phys. Soc.*, Edin., 1880.

[2] The late Mr. Searles V. Wood, in an able summary of the possible causes of the succession of cold and warm climates in the northern hemisphere, enumerates no fewer than seven theories which have met with more or less acceptance. These are:—

(1) The gradual cooling of the earth from a condition of original incandescence.

(2) Changes in the obliquity of the ecliptic.

(3) Changes in the position of the earth's axis of rotation.

(4) The effect of the precession of the equinoxes along with changes of the eccentricity of the earth's orbit.

(5) Variations in the amount of heat given off by the sun.

(6) Differences in the temperature of portions of space passed through by the earth.

(7) Differences in the distribution of land and water in connection with the flow of oceanic currents.

[3] Von Woeikoff has very strongly put these principles in a review of Croll's recent book, "Climate and Cosmology," *American Journal of Science*, March 1886.

At the present time the North Atlantic presents some very peculiar, and in some respects exceptional, features, which are most instructive with reference to its past history. The great internal plateau of the American continent is now dry land; the passage across Central America between the Atlantic and Pacific is blocked; the Atlantic opens very widely to the north; the high mass of Greenland towers in its northern part. The effects are that the great equatorial current running across from Africa and embayed in the Gulf of Mexico, is thrown northward and eastward in the Gulf Stream, acting as a hot-water apparatus to heat up to an exceptional degree the western coast of Europe. On the other hand, the cold Arctic current from the Polar seas is thrown to the westward, and runs down from Greenland past the American shore.[1] The pilot chart for June of this year shows vast fields of drift ice on the western side of the Atlantic as far south as the latitude of 40°. So far, therefore, the Glacial age in that part of the Atlantic still extends; this at a time when, on the eastern side of the Atlantic, the culture of cereals reaches in Norway beyond the Arctic Circle. Let us inquire into some of the details of these phenomena.

The warm water thrown into the North Atlantic not only increases the temperature of its whole waters, but gives an exceptionally mild climate to Western Europe. Still the countervailing influence of the Arctic currents and the Greenland ice is sufficient to permit icebergs which creep down to the mouth of the Strait of Belle Isle, in the latitude of the south of England, to remain unmelted till the snows of a succeeding winter fall upon them. Now let us suppose that a subsidence of land in tropical America were to allow the equatorial current to pass through into the Pacific. The effect would at once be to reduce the temperature of Norway and Britain to that of Greenland and Labrador at present, while the latter countries would themselves become colder. The northern ice, drifting down into the Atlantic, would not, as now, be melted rapidly by the warm water which it meets in the Gulf Stream. Much larger quantities of it would remain undissolved in summer, and thus an accumulation of permanent ice would take place, along the American coast at first, but probably at length even on the European side. This would still further chill the atmosphere, glaciers would be established on all the mountains of temperate Europe and America,[2] the summer would be kept cold by melting ice and snow, and at length all Eastern America and Europe might become uninhabitable, except by Arctic animals and plants, as far south as perhaps 40° of north latitude. This would be simply a return of the Glacial age. I have assumed only one geographical change; but other and more complete changes of subsidence and elevation might take place, with effects on climate still more decisive; more especially would this be the case if there were a considerable submergence of the land in temperate latitudes.

We may suppose an opposite case. The high plateau of Greenland might subside, or be reduced in height, and the openings of Baffin's Bay and the North Atlantic might be closed. At the same time the interior plain of America might be depressed, so that, as we know to have been the case in the Cretaceous period, the warm waters of the Mexican Gulf would circulate as far north as the basins of the present great American lakes. In these circumstances there would be an immense diminution of the sources of floating ice, and a correspondingly vast increase in the surface of warm water. The effects would be to enable a temperate flora to subsist in Greenland, and to bring all the present temperate regions of Europe and America into a condition of subtropical verdure.

It is only necessary to add that we know that vicissitudes not dissimilar from those above sketched have actually occurred in comparatively recent geological times, to enable us to perceive that we can dispense with all other causes of change of climate, though admitting that some of them may have occupied a secondary place.[3] This will give us, in dealing with the distribution of life, the great advantage of not being tied up to definite astronomical cycles of glaciation, which may not always suit the geological facts, and of correlating elevation and subsidence of the land with changes of climate affecting living beings. It

[1] I may refer here to the admirable expositions of these effects by the late Dr. Carpenter in his papers on the results of the explorations of the *Challenger*.

[2] According to Bonney, the west coast of Wales is about 12° above the average for its latitude, and if reduced to 12 below the average its mountains would have large glaciers.

[3] More especially the ingenious and elaborate arguments of Croll deserve consideration; and, though I cannot agree with him in his main thesis, I gladly acknowledge the great utility of the work he has done.

will, however, be necessary, as Wallace well insists, that we shall hold to that degree of fixity of the continents in their position, notwithstanding the submergences and emergences they have experienced, to which I have already adverted. Sir Charles Lyell, more than forty years ago, published in his "Principles of Geology" two imaginary maps which illustrate the extreme effects of various distribution of land and water. In one all the continental masses are grouped around the equator. In the other they are all placed around the poles, leaving an open equatorial ocean. In the one case the whole of the land and its inhabitants would enjoy a perpetual summer, and scarcely any ice could exist in the sea. In the other the whole of the land would be subjected to an Arctic climate, and it would give off immense quantities of ice to cool the ocean. But Lyell did not suppose that any such distribution as that represented in his maps had actually occurred, though this supposition has been sometimes attributed to him. He merely put what he regarded as an extreme case to illustrate what might occur under conditions less exaggerated. Sir Charles, like other thoughtful geologists, was well aware of the general fixity of the areas of the continents, though with great modifications in the matter of submergence and of land conditions. The union, indeed, of these two great principles of fixity and diversity of the continents lies at the foundation of theoretical geology.

We can now more precisely indicate this than was possible when Lyell produced his "Principles," and can reproduce the conditions of our continents in even the more ancient periods of their history. Some examples may be taken from the history of the American continent, which is more simple in its arrangements than the double continent of Europ-asia. We may select the early Devonian or Erian period, in which the magnificent flora of that age—the earliest certainly known to us—made its appearance. Imagine the whole interior plain of North America submerged, so that the continent is reduced to two strips on the east and west, connected by a belt of Laurentian land on the north. In the great mediterranean sea thus produced, the tepid water of the equatorial current circulated, and it swarmed with corals, of which we know no less than 150 species, and with other forms of life appropriate to warm seas. On the islands and coasts of this sea was introduced the Erian flora, appearing first in the north; and with that vitality and colonising power of which, as Hooker has well shown, the Scandinavian flora is the best modern type, spreading itself to the south.[1] A very similar distribution of land and water in the Cretaceous age gave a warm and equable climate in those portions of North America not submerged, and coincided with the appearance of the multitude of broad-leaved trees of modern types introduced in the early and middle Cretaceous, and which prepared the way for the mammalian life of the Eocene. We may take a still later instance from the second continental period of the later Pleistocene or early modern, when there would seem to have been a partial or entire closure of the North Atlantic against the Arctic ice, and wide extensions seaward of the European and American land, with possibly considerable tracts of land in the vicinity of the equator, while the Mediterranean and the Gulf of Mexico were deep inland lakes (Dawkins, *Popular Science Monthly*, 1873). The effect of such conditions on the climates of the northern hemisphere must have been prodigious, and their investigation is rendered all the more interesting because it would seem that this continental period of the post-Glacial age was that in which man made his first acquaintance with the coasts of the Atlantic, and possibly made his way across its waters.

We have in America ancient periods of cold as well as of warmth. I have elsewhere referred to the boulder conglomerates of the Huronian, of the Cambrian and Ordovician, of the Millstone-grit period of the Carboniferous and of the early Permian, but would not venture to affirm that either of these periods was comparable in its cold with the later Glacial age, still less with that imaginary age of continental glaciation assumed by certain of the more extreme theorists ("Notes on Post-Pliocene of Canada"; "Pre-Cambrian Glaciers," *Geol. Mag.*, 1880). These ancient conglomerates were probably produced by floating ice, and this at periods when in areas not very remote temperate floras and faunas could flourish. The glacial periods of our old continent occurred in times when the surface of the submerged land was opened up to the northern currents, drifting over it mud and sand and stones, and rendering nugatory, in so far at least as the bottom of the sea was concerned, the effects of the superficial warm streams. Some of these beds are also peculiar to the eastern margin of the continent, and indicate ice-drift along the Atlantic coast in the same manner as at present, while conditions of greater warmth existed in the interior. Even in the more recent Glacial age, while the mountains were covered with snow and the lowlands submerged under a sea laden with ice, there were interior tracts in somewhat high latitudes of America in which hardy forest trees and herbaceous plants flourished abundantly; and these were by no means exceptional "interglacial" periods. Thus we can show that, while from the remote Huronian period to the Tertiary the American land occupied the same position as at present, and while its changes were merely changes of relative level as compared with the sea, these have so influenced the ocean currents as to cause great vicissitudes of climate.

Without entering on any detailed discussion of that last and greatest Glacial period which is best known to us, and is more immediately connected with the early history of man and the modern animals, it may be proper to make a few general statements bearing on the relative importance of sea-borne and land ice in producing those remarkable phenomena attributable to ice action in this period. In considering this question it must be borne in mind that the greater masses of floating ice are produced at the seaward extremities of land glaciers, and that the heavy field-ice of the Arctic regions is not so much a result of the direct freezing of the surface of the sea as of the accumulation of snow precipitated on the frozen surface. In reasoning on the extent of ice action, and especially of glaciers in the Pleistocene age, it is necessary to keep this fully in view. Now in the formation of glaciers at present—and it would seem also in any conceivable former state of the earth—it is necessary that extensive evaporation should conspire with great condensation of water in the solid form. Such conditions exist in mountainous regions sufficiently near to the sea, as in Greenland, Norway, the Alps, and the Himalayas; but they do not exist in low Arctic lands like Siberia or Grinnell Land, nor in inland mountains. It follows that land-glaciation has narrow limits, and that we cannot assume the possibility of great confluent or continental glaciers covering the interior of wide tracts of land. No imaginable increase of cold could render this possible, inasmuch as there could not be a sufficient influx of vapour to produce the necessary condensation; and the greater the cold, the less would be the evaporation. On the other hand, any increase of heat would be felt more rapidly in the thawing and evaporation of land ice and snow than on the surface of the sea.

Applying these very simple geographical truths to the North Atlantic continents, it is easy to perceive that no amount of refrigeration could produce a continental glacier, because there could not be sufficient evaporation and precipitation to afford the necessary snow in the interior. The case of Greenland is often referred to, but this is the case of a high mass of cold land with sea, mostly open, on both sides of it, giving, therefore, the conditions most favourable to precipitation of snow. If Greenland were less elevated, or if there were dry plains around it, the case would be quite different, as Nares has well shown by his observations on the summer verdure of Grinnell Land, which, in the immediate vicinity of North Greenland, presents very different conditions as to glaciation and climate.[1] If the plains were submerged, and the Arctic currents allowed free access to the interior of the continent of America, it is conceivable that the mountainous regions remaining out of water would be covered with snow and ice, and there is the best evidence that this actually occurred in the Glacial period; but with the plains out of water this would be impossible. We see evidence of this at the present day in the fact that in unusually cold winters the great precipitation of snow takes place south of Canada, leaving the north comparatively bare, while as the temperature becomes milder the area of snow deposit moves farther to the north. Thus a greater extension of the Atlantic, and especially of its cold ice-laden Arctic currents, becomes the most potent cause of a glacial age.

I have long maintained these conclusions on general geographical grounds, as well as on the evidence afforded by the Pleistocene deposits of Canada; and in an address the theme of

[1] As I have elsewhere endeavoured to show ("Report on Silurian and Devonian Plants of Canada"), a warm climate in the Arctic region seems to have afforded the necessary conditions for the great colonising floras of all geological periods. Gray had previously illustrated the same fact in the case of the more modern floras.

[1] These views have been admirably illustrated by Von Woeikoff in the paper already referred to, and in previous geographical papers.

which is the ocean I may be excused for continuing to regard the supposed terminal moraines of great continental glaciers as nothing but the southern limit of the ice-drift of a period of submergence. In such a period the southern margin of an ice-laden sea where its floe-ice and bergs grounded, or where its ice was rapidly melted by warmer water, and where consequently its burden of boulders and other debris was deposited, would necessarily present the aspect of a moraine, which by the long continuance of such conditions might assume gigantic dimensions. Let it be observed, however, that I fully admit the evidence of the great extension of local glaciers in the Pleistocene age, and especially in the times of partial submergence of the land.

I am quite aware that it has been held by many able American geologists[1] that in North America a continental glacier extended in temperate latitudes from sea to sea, or at least from the Atlantic to the Rocky Mountains, and that this glacier must, in many places, have exceeded a mile in thickness. The reasons above stated appear, however, sufficient to compel us to seek for some other explanation of the observed facts, however difficult this may at first sight appear. With a depression such as we know to have existed, admitting the Arctic currents along the St. Lawrence Valley, through gaps in the Laurentian watershed, and down the great plains between the Laurentian areas and the Rocky Mountains, we can easily understand the covering of the hills of Eastern Canada and New England with ice and snow, and a similar covering of the mountains of the west coast. The sea also in this case might be ice-laden and boulder-bearing as far south as 40°, while there might still be low islands far to the north on which vegetation and animals continued to exist. We should thus have the conditions necessary to explain all the anomalies of the glacial deposits. Even the glaciation of high mountains south of the St. Lawrence Valley would then become explicable by the grounding of floe-ice on the tops of these mountains when reefs in the sea. In like manner we can understand how on the isolated trappean hill of Belœil, in the St. Lawrence Valley, Laurentian boulders far removed from their native seats to the north are perched at a height of about 1200 feet on a narrow peak where no glacier could possibly have left them. The so-called moraine, traceable from the great Missouri Coteau in the west to the coasts of New Jersey, would thus become the mark of the western and southern limit of the subsidence, or of the line along which the cold currents bearing ice were abruptly cut off by warm surface waters. I am glad to find that these considerations are beginning to have weight with European geologists in their explanation of the glacial drift of the great plains of Northern Europe.

Whatever difficulties may attend such a supposition, they are small compared with those attendant on the belief of a continental glacier, moving without the aid of gravity, and depending for its material on the precipitation taking place on the interior plains of a great continent.

I have elsewhere endeavoured to show, on the evidence found in Canada, that the occurrence of marine shells, land plants, and insects in the glacial deposits of that country indicates not so much the effect of general interglacial periods as the local existence of conditions like those of Grinnell Land and Greenland, in proximity to each other at one and the same period, and depending on the relative levels of land and the distribution of ocean currents and ice-drift.[2]

I am old enough to remember the sensation caused by the delightful revelations of Edward Forbes respecting the zones of animal life in the sea, and the vast insight which they gave into the significance of the work on minute organisms previously done by Ehrenberg, Lonsdale, and Williamson, and into the meaning of fossil remains. A little later the soundings for the Atlantic cable revealed the chalky foraminiferal ooze of the abyssal ocean; still more recently the wealth of facts disclosed by the *Challenger* voyage, which naturalists have not yet had time to digest, have opened up to us new worlds of deep-sea life.

The bed of the deep Atlantic is covered for the most part by a mud or ooze largely made up of the debris of Foraminifera and other minute organisms mixed with fine clay. In the North Atlantic the Norwegian naturalists call this Biloculina mud. Further south the *Challenger* naturalists speak of it as Globigerina ooze. In point of fact it contains different species of foraminiferal shells, Globigerina and Orbulina being in some localities dominant, and in others other species, and these changes are more apparent in the shallower portions of the ocean.

It is also to be observed that there are means for disseminating coarse material over the ocean bed. There are in the line of the Arctic current on the American coast great sand-banks, and off the coast of Norway sand constitutes a considerable part of the bottom material. Soundings and dredgings off Great Britain, and also off the American coast, have shown that fragments of stone referable to Arctic lands are abundantly strewn over the bottom along certain lines, and the Antarctic continent, otherwise almost unknown, makes its presence felt to the dredge by the abundant masses of crystalline rock drifted far from it to the north. These are not altogether new discoveries. I had inferred many years ago, from stones taken up by the hooks of fishermen on the banks of Newfoundland, that rocky material from the north is dropped on these banks by the heavy ice which drifts over them every spring, that these stones are glaciated, and that after they fall to the bottom sand is drifted over them with sufficient velocity to polish the stones and to erode the shelly coverings of Arctic animals attached to them ("Notes on Post-Pliocene of Canada," 1872). If then the Atlantic basin were upheaved into land we should see beds of sand, gravel, and boulders with clay flats and layers of marl and limestone. According to the *Challenger* Reports, in the Antarctic seas south of 64° there is blue mud with fragments of rock in depths of 1200 to 2000 fathoms. The stones, some of them glaciated, were granite, diorite, amphibolite, mica-schist, gneiss, and quartzite. This deposit ceases and gives place to Globigerina ooze and red clay at 46° to 47° S., but even further north there is sometimes as much as 49 per cent. of crystalline sand. In the Labrador current a block of syenite weighing 490 pounds was taken up from 1340 fathoms, and in the Arctic current, 100 miles from land, was a stony deposit, some stones being glaciated. Among these were smoky quartz, quartzite, limestone, dolomite, mica-schist, and serpentine; also particles of monoclinic and triclinic feldspar, hornblende, augite, magnetite, mica, and glauconite, the latter no doubt formed in the sea-bottom, the others drifted from Eozoic and Palæozoic formations to the north ("General Report, *Challenger* Expedition").

A remarkable fact in this connection is that the great depths of the sea are as impassable to the majority of marine animals as the land itself. According to Murray, while twelve of the *Challenger's* dredgings taken in depths greater than 2000 fathoms gave 92 species, mostly new to science, a similar number of dredgings in shallower water near the land gave no less than 1000 species. Hence arises another apparent paradox relating to the distribution of organic beings. While at first sight it might seem that the chances of wide distribution are exceptionally great for marine species, this is not so. Except in the case of those which enjoy a period of free locomotion when young, or are floating and pelagic, the deep ocean sets bounds to their migrations. On the other hand, the spores of cryptogamic plants may be carried for vast distances by the wind, and the growth of volcanic islands may effect connections which, though only temporary, may afford opportunity for land animals and plants to pass over.

But I must here call your attention to still another geological paradox, namely, that the deep sea, which is so great a barrier to the passage of the shallow-water animals, seems, under certain conditions, to afford facilities for the transmission of land animals and plants. The connections established by the observations of the *Challenger*, and so well expounded by Wallace and Hemsley ("Continental and Island Life"; "Botany of the *Challenger* Expedition"), between the floras of oceanic islands and the continents, establish this conclusively. Thus the Bermudas, altogether recent islands, have been stocked by the agency chiefly of the ocean currents and of birds, with nearly 150 species of continental plants, and the facts collected by Hemsley as to the present facilities of transmission, along with the evidence afforded by older oceanic islands which have been receiving animal and vegetable colonists for longer periods, go far to show that, time being given, the sea actually affords facilities for the migrations of the inhabitants of the land, greater than those of continuous continents.

With reference to the transmission of living beings across the Atlantic, we have before us the remarkable fact that from the Cambrian age onwards there were on the two sides of the ocean many species of invertebrate animals which were either

[1] Report of Mr. Carvill Lewis in "Pennsylvania Geological Survey," 1884; also Dana's "Manual."

[2] "Notes on Post-Pliocene of Canada," 1872. One well-marked interval only has been established in the glacial deposits of Canada.

identical or so closely allied as to be possibly varietal forms.[1] In like manner the early plants of the Upper Silurian, Devonian, and Carboniferous present many identical species; but this identity becomes less marked in the vegetation of the more modern times.

In so far as plants are concerned, it is to be observed that the early forests were largely composed of cryptogamous plants, and the spores of these in modern times have proved capable of transmission for great distances. In considering this we cannot fail to conclude that the union of simple cryptogamous fructification with arboreal stems of high complexity, so well illustrated by Dr. Williamson, had a direct relation to the necessity for a rapid and wide distribution of these ancient trees. It seems also certain that some spores, as, for example, those of the Rhizocarps (see paper by the author on "Palæozoic Rhizocarps," *Chicago Transactions*, 1886), a type of vegetation abundant in the Palæozoic, and certain kinds of seeds, as those named *Ætheotesta* and *Pachytheca*, were fitted for flotation. Further, the periods of Arctic warmth permitted the passage around the northern belt of many temperate species of plants, just as now happens with the Arctic flora; and when these were dispersed by colder periods they marched southward along both sides of the sea on the mountain-chains.

The same remark applies to northern forms of marine invertebrates, which are much more widely distributed in longitude than those further south. The late Mr. Gwyn Jeffreys, in one of his latest communications to this Association, stated that 54 per cent. of the shallow-water mollusks of New England and Canada are also European, and of the deep-sea forms 30 out of 35; these last of course enjoying greater facilities for migration than those which have to travel slowly along the shallows of the coasts in order to cross the ocean and settle themselves on both sides. Many of these animals, like the common mussel and sand clam, are old settlers which came over in the Pleistocene period, or even earlier. Others, like the common periwinkle, seem to have been slowly extending themselves in modern times, perhaps even by the agency of man. The older immigrants may possibly have taken advantage of lines of coast now submerged, or of warm periods, when they could creep around by the Arctic shores. Mr. Herbert Carpenter and other naturalists employed on the *Challenger* collections have made similar statements respecting other marine invertebrates, as, for instance, the Echinoderms, of which the deep-sea crinoids present many common species, and my own collections prove that many of the shallow-water forms are common. Dall ("Report on Alaska") and Whiteaves (*Transactions R. S. C.*) have shown that some mollusks and Echinoderms are common even to the Atlantic and Pacific coasts of North America; a remarkable fact, testifying at once to the fixity of these species and to the manner in which they have been able to take advantage of geographical changes. Some of the species of whelks common to the Gulf of St. Lawrence and the Pacific are animals which have no special locomotive powers even when young, but they are northern forms not proceeding far south, so that they may have passed through the Arctic seas. In this connection it is well to remark that many species of animals have powers of locomotion when young which they lose when adult, and that others may have special means of transit. I once found at Gaspé a specimen of the Pacific species of Coronula, or whale-barnacle, the *C. reginæ* of Darwin, attached to a whale taken in the Gulf of St. Lawrence, and which had probably succeeded in making that passage around the north of America which so many navigators have essayed in vain.

It is to be remarked here that while many plants and marine invertebrates are common to the two sides of the Atlantic, it is different with land animals, and especially vertebrates. I do not know that any fossil insects or land-snails or millipedes of Europe and America are specifically identical, and of the numerous species of batrachians of the Carboniferous and reptiles of the Mesozoic all seem to be distinct on the two sides. The same appears to be the case with the Tertiary mammals, until in the later stages of that great period we find such genera as the horse, the camel, and the elephant appearing on the two sides of the Atlantic; but even then the species seem different, except in the case of a few northern forms.

[1] See Davidson's "Monographs on Brachiopods": Etheridge, "Address to Geological Society of London"; Woodward, "Address to Geologists' Association"; also Barrande's "Special Memoirs on the Brachiopods, Cephalopods, &c."; Hall, "Palæontology of New York"; Billings, "Reports on Canadian Fossils"; and Matthews, "Cambrian of New Brunswick," *Trans. R.S.C.*

Some of the longer-lived mollusks of the Atlantic furnish suggestions which remarkably illustrate the biological aspect of these questions. Our familiar friend the oyster is one of these. The first known oysters appear in the Carboniferous in Belgium and in the United States of America. In the Carboniferous and Permian they are few and small, and they do not culminate till the Cretaceous, in which there are no less than ninety-one so-called species in America alone; but some of the largest known species are found in the Eocene. The oyster, though an inhabitant of shallow water, and very limitedly locomotive when young, has survived all the changes since the Carboniferous age, and has spread itself over the whole northern hemisphere (White, "Report U.S. Geol. Survey, 1882-83").

I have collected fossil oysters in the Cretaceous clays of the *coulées* of Western Canada, in the Lias shales of England, in the Eocene and Cretaceous beds of the Alps, of Egypt, of the Red Sea coast, of Judæa, and the heights of Lebanon. Everywhere and in all formations they present forms which are so variable and yet so similar that one might suppose all the so-called species to be mere varieties. Did the oyster originate separately on the two sides of the Atlantic, or did it cross over so promptly that its appearance seems to be identical on the two sides? Are all the oysters of a common ancestry, or did the causes, whatever they were, which introduced the oyster in the Carboniferous act over again in later periods? Who can tell? This is one of the cases where causation and development—the two scientific factors which constitute the basis of what is vaguely called evolution—cannot easily be isolated. I would recommend to those biologists who discuss these questions to addict themselves to the oyster. This familiar mollusk has successfully pursued its course and has overcome all its enemies, from the flat-toothed selachians of the Carboniferous, to the oyster-dredgers of the present day, has varied almost indefinitely, and yet has continued to be an oyster, unless indeed it may at certain portions of its career have temporarily assumed the disguise of a Gryphæa or an Exogyra. The history of such an animal deserves to be traced with care, and much curious information respecting it will be found in the report which I have cited.

But in these respects the oyster is merely an example of many forms. Similar considerations apply to all those Pliocene and Pleistocene mollusks which are found in the raised sea-bottoms of Norway and Scotland, on the top of Moel Tryfaen in Wales, and at similar great heights on the hills of America, many of which can be traced back to early Tertiary times, and can be found to have extended themselves all over the seas of the northern hemisphere. They apply in like manner to the ferns, the conifers, and the angiosperms, many of which we can now follow without even specific change to the Eocene and Cretaceous. They all show that the forms of living things are more stable than the lands and seas in which they live. If we were to adopt some of the modern ideas of evolution, we might cut the Gordian knot by supposing that, as like causes can produce like effects, these types of life have originated more than once in geological time, and need not be genetically connected with each other. But while evolutionists repudiate such an application of their doctrine, however natural and rational, it would seem that nature still more strongly repudiates it, and will not allow us to assume more than one origin for one species. Thus the great question of geographical distribution remains in all its force, and, by still another of our geological paradoxes, mountains become ephemeral things in comparison with the delicate herbage which covers them, and seas are in their present extent but of yesterday when compared with the minute and feeble organisms that creep on their sands or swim in their waters.

The question remains, Has the Atlantic achieved its destiny and finished its course, or are there other changes in store for it in the future? The earth's crust is now thicker and stronger than ever before, and its great ribs of crushed and folded rock are more firm and rigid than in any previous period. The stupendous volcanic phenomena manifested in Mesozoic and early Tertiary times along the borders of the Atlantic have apparently died out. These facts are in so far guarantees of permanence. On the other hand, it is known that movements of elevation along with local depression are in progress in the Arctic regions, and a great weight of new sediment is being deposited along the borders of the Atlantic, especially on its western side, and this is not improbably connected with the earthquake shocks and slight movements of depression which have occurred in North America. It is possible that these slow and secular movements may go on uninterruptedly until

considerable changes are produced; but it is quite as likely that they may be retarded or reversed.

It is possible, on the other hand, that after the long period of quiescence which has elapsed there may be a new settlement of the ocean bed, accompanied with foldings of the crust, especially on the western side of the Atlantic, and possibly with renewed volcanic activity on its eastern margin. In either case a long time relatively to our limited human chronology may intervene before the occurrence of any marked change. On the whole, the experience of the past would lead us to expect movements and eruptive discharges in the Pacific rather than in the Atlantic area. It is therefore not unlikely that the Atlantic may remain undisturbed, unless secondarily and indirectly, until after the Pacific area shall have attained to a greater degree of quiescence than at present. But this subject is one too much involved in uncertainty to warrant us in following it further.

In the meantime the Atlantic is to us a practically permanent ocean, varying only in its tides, its currents, and its winds, which science has already reduced to definite laws, so that we can use if we cannot regulate them. It is ours to take advantage of this precious time of quietude, and to extend the blessings of science and of our Christian civilisation from shore to shore until there shall be no more sea, not in the sense of that final drying-up of old Ocean to which some physicists look forward, but in the higher sense of its ceasing to be the emblem of unrest and disturbance, and the cause of isolation.

I must now close this address with a short statement of the general objects which I have had in view in directing your attention to the geological development of the Atlantic. We cannot, I think, consider the topics to which I have referred without perceiving that the history of ocean and continent is an example of progressive design, quite as much as that of living beings. Nor can we fail to see that, while in some important directions we have penetrated the great secret of Nature, in reference to the general plan and structure of the earth and its waters, and the changes through which they have passed, we have still very much to learn, and perhaps quite as much to unlearn, and that the future holds out to us and to our successors higher, grander, and clearer conceptions than those to which we have yet attained. The vastness and the might of Ocean, and the manner in which it cherishes the feeblest and most fragile beings, alike speak to us of Him who holds it in the hollow of His hand, and gave to it of old its boundaries and its laws; but its teaching ascends to a higher tone when we consider its origin and history, and the manner in which it has been made to build up continents and mountain-chains, and at the same time to nourish and sustain the teeming life of sea and land.

SECTION A

MATHEMATICAL AND PHYSICAL SCIENCE

Opening Address by Prof. G. H. Darwin, M.A., LL.D., F.R.S., F.R.A.S., President of the Section

A mere catalogue of facts, however well arranged, has never led to any important scientific generalisation. For in any subject the facts are so numerous and many sided that they only lead us to a conclusion when they are marshalled by the light of some leading idea. A theory is, then, a necessity for the advance of science, and we may regard it as the branch of a living tree, of which facts are the nourishment. In the struggle between competing branches to reach the light some perish, and others form vigorous limbs. And as in a tree the shape of the young shoot can give us but little idea of the ultimate form of the branch, so theories become largely transformed in the course of their existence, and afford in their turn the parent stem for others.

The success of a theory may be measured by the extent to which it is capable of assimilating facts, and by the smallness of the change which it must undergo in the process. Every theory which is based on a true perception of facts is to some extent fertile in affording a nucleus for the aggregation of new observations. And a theory, apparently abandoned, has often ultimately appeared to contain an element of truth, which receives acknowledgment by the light of later views.

It will, I think, be useful to avail myself of the present occasion to direct your attention to a certain group of theories which are still in an undeveloped and somewhat discordant condition, but which must form the nucleus round which many observations have yet to be collected before these theories and their descendants can make a definitely accepted body of truth. If I am disposed to criticise some of them in their actual form, I shall not be understood as denying the great service which has been rendered to science by their formulation.

Great as have been the advances of geology during the present century, we have no precise knowledge of one of its fundamental units. The scale of time on which we must suppose geological history to be drawn is important not only for geology itself, but it has an intimate relation with some of the profoundest questions of biology, physics, and cosmogony.

We can hardly hope to obtain an accurate measure of time from pure geology, for the extent to which the events chronicled in strata were contemporaneous is not written in the strata themselves, and there are long intervals of time of which no record has been preserved.

An important step has been taken by Alfred Tylor, Croll, and others, towards the determination of the rate of action of geological agents (Geikie, "Text-book of Geology," 1882, p. 442). From estimates of the amount of sediment carried down by rivers, it appears that it takes from 1000 to 6000 years to remove one foot of rock from the general surface of a river basin.

From a consideration of the denuding power of rivers, and a measurement of the thickness of stratified rock, Phillips has made an estimate of the period of time comprised in geological history, and finds that, from stratigraphical evidence alone, we may regard the antiquity of life on the earth as being possibly between 38 and 96 millions of years ("Life on the Earth," Rede Lecture, 1860, p. 119).

Now while we should perhaps be wrong to pay much attention to these figures, yet at least we gain some insight into the order of magnitude of the periods with which we have to deal, and we may feel confident that a million years is not an infinitesimal fraction of the whole of geological time.

It is hardly to be hoped, however, that we shall ever attain to any very accurate knowledge of the geological time scale from this kind of argument.

But there is another theory which is precise in its estimate, and which, if acceptable from other points of view, will furnish exactly what is requisite. Mr. Croll claims to prove that great changes of climate must be brought about by astronomical events of which the dates are known or ascertainable ("Climate and Time"). The perturbation of the planets causes a secular variability in the eccentricity of the earth's orbit, and we are able confidently to compute the eccentricity of many thousands of years forward and backward from to-day, although it appears that, in the opinion of Newcomb and Adams, no great reliance can be placed on the values deduced from the formulæ at dates so remote as those of which Mr. Croll speaks. According to Mr. Croll, when the eccentricity of the earth's orbit is at its maximum, that hemisphere which has its winter in aphelion would undergo a glacial period. Now, as the date of great eccentricity is ascertainable, this would explain the great Ice Age and give us its date.

The theory has met with a cordial acceptance on many sides, probably to a great extent from the charm of the complete answer it affords to one of the great riddles of geology.

Adequate criticism of Mr. Croll's views is a matter of great difficulty on account of the diversity of causes which are said to co-operate in the glaciation. In the case of an effect arising from a number of causes, each of which contributes its share, it is obvious that if the amount of each cause and of each effect is largely conjectural the uncertainty of the total result is by no means to be measured by the uncertainty of each item, but is enormously augmented. Without going far into details it may be said that these various concurrent causes result in one fundamental proposition with regard to climate, which must be regarded as the keystone of the whole argument. That proposition amounts to this—that climate is unstable.

Mr. Croll holds that the various causes of change of climate operate *inter se* in such a way as to augment their several efficiencies. Thus the trade-winds are driven by the difference of temperature between the frigid and torrid zones, and if from the astronomical cause the northern hemisphere becomes cooler the trade-winds on that hemisphere encroach on those of the other, and the part of the warm oceanic current which formerly flowed into the cold north zone, will be diverted into the southern hemisphere. Thus the cold of the northern hemisphere is augmented, and this in its turn displaces the trade-winds further, and this again acts on the ocean currents, and so on; and this is neither more nor less than instability.

But if climate be unstable, and if, from some of those temporary causes for which no reasons can as yet be assigned, there occurs a short period of cold, then surely some even infinitesimal portion of the second link in the chain of causation must exist; and this should proceed as in the first case to augment the departure from the original condition, and the climate must change.

In a matter so complex as the weather, it is at least possible that there should be instability when the cause of disturbance is astronomical, whilst there is stability in an ordinary sense. If this is so, it might be explained by the necessity for a prolonged alteration in the direction of prevailing winds in order to affect oceanic currents (Zöppritz, *Phil. Mag.* 1878).

However this may be, so remarkable a doctrine as the instability of climate must certainly be regarded with great suspicion, and we should require abundant proof before accepting it. Now there is one result of Mr. Croll's theory which should afford almost a crucial test of its acceptability. In consequence of the precession of the equinoxes the conditions producing glaciation in one hemisphere must be transferred to the other every 10,000 years. If there is good geological evidence that this has actually been the case, we should allow very great weight to the astronomical theory, notwithstanding the difficulties in its way. Mr. Croll has urged that there is such evidence, and this view has been recently strongly supported by M. Blytt (NATURE, July 8 and 15, 1886). Other geologists do not, however, seem convinced of the conclusiveness of the evidence.

Thus Mr. Wallace ("Island Life"), whilst admitting that there was some amelioration of climate from time to time during the last glacial period, cannot agree in the regular alternations of cold and warm demanded by Mr. Croll's theory. To meet this difficulty he proposes a modification. According to his view, large eccentricity in the earth's orbit will only produce glaciation when accompanied by favourable geographical conditions. And when extreme glaciation has once been established in the hemisphere which has its winter in aphelion, the glaciation will persist, with some diminution of intensity, when precession has brought round the perihelion to the winter. In this case, according to Wallace, glaciation will be simultaneous on both hemispheres.

Again, he contends that, if the geographical conditions are not favourable, astronomical causes alone are not competent to produce glaciation.

There is agreement between the two theories in admitting instability of climate at first, when glaciation is about to begin under the influence of great eccentricity of the orbit, but afterwards Wallace demands great stability of climate. Thus he maintains that there is great stability in extreme climates, either warm or cold, whilst there is instability in moderate climates. I cannot perceive that we have much reason from physical considerations for accepting these remarkable propositions, and the acceptance or rejection of them demands an accurate knowledge of the most nicely balanced actions, of which we have as yet barely an outline.

Ocean currents play a most prominent part in these theories, but at this moment our knowledge of the principal oceanic circulation, and of its annual variability, is very meagre. In the course of a few years we may expect a considerable accession to our knowledge, when the Meteorological Office shall have completed a work but just begun—viz. the analysis of ships' logs for some sixty years, for the purpose of laying down in charts the oceanic currents.

With regard to the great atmospheric currents even the general scheme is not yet known. Nearly thirty years ago Prof. James Thomson gave before this Association at Dublin an important suggestion on this point. As it has been passed over in complete silence ever since, the present seems to be a good opportunity of redirecting attention to it.

According to Halley's theory of atmospheric circulation, the hot air rises at the equator and floats north and south in two grand upper currents, and it then acquires a westward motion relatively to the earth's surface, in consequence of the earth's rotation. Also the cold air at the pole sinks and spreads out over the earth's surface in a southerly current, at first with a westerly tendency, because the air comes from the higher regions of the atmosphere, and afterwards due south, and then easterly, when it is left behind by the earth in its rotation.

Now Prof. Thomson remarks that this theory disagrees with fact in as far as that in our latitudes, the winds, though westerly, have a poleward tendency, instead of the reverse.

In the face of this discrepancy he maintains that "the great circulation already described does actually occur, but occurs subject to this modification, that a thin stratum of air on the surface of the earth in the latitudes higher than 30°—a stratum in which the inhabitants of those latitudes have their existence, and of which the movements constitute the observed winds of those latitudes—being, by friction and impulses on the surface of the earth, retarded with reference to the rapid whirl or vortex-motion from west to east of the great mass of air above it, tends to flow towards the pole, and actually does so flow to supply the partial void in the central parts of that vortex due to the centrifugal force of its revolution. Thus it appears that in the temperate latitudes there are three currents at different heights—that the uppermost moves towards the pole, and is part of a grand primary circulation between equatorial and polar regions; that the lowermost moves also towards the pole, but is only a thin stratum forming part of a secondary circulation; that the middle current moves from the pole, and constitutes the return current for both the preceding; and that all these three currents have a prevailing motion from west to east" (Brit. Assoc. *Report*, Dublin, 1857, pp. 38, 39).

Such, then, appears to be our present state of ignorance of these great terrestrial actions, and any speculations as to the precise effect of changes in the annual distribution of the sun's heat must be very hazardous until we know more precisely the nature of the thing changed.

When looking at the astronomical theory of geological climate as a whole, one cannot but admire the symmetry and beauty of the scheme, and nourish a hope that it may be true; but the mental satisfaction derived from our survey must not blind us to the doubts and difficulties with which it is surrounded.

And now let us turn to some other theories bearing on this important point of geological time.

Amongst the many transcendent services rendered to science by Sir William Thomson, it is not the least that he has turned the searching light of the theory of energy on to the science of geology. Geologists have thus been taught that the truth must lie between the cataclysms of the old geologists and the uniformitarianism of forty years ago. It is now generally believed that we must look for a greater intensity of geologic action in the remote past, and that the duration of the geologic ages, however little we may be able mentally to grasp their greatness, must bear about the same relation to the numbers which were written down in the older treatises on geology, as the life of an ordinary man does to the age of Methuselah.

The arguments which Sir William Thomson has adduced in limitation of geological time are of three kinds. I shall refer first to that which has been called the argument from tidal friction; but before stating the argument itself it will be convenient to speak of the data on which the numerical results are based.

Since water is not frictionless, tidal oscillations must be subject to friction, and this is evidenced by the delay of twenty-four to thirty-six hours which is found to occur between full and change of moon and spring-tide. An inevitable result of this friction is that the diurnal rotation of the earth must be slowly retarded, and that we who accept the earth as our timekeeper must accuse the moon of a secular acceleration of her motion round the earth, which cannot be otherwise explained. It is generally admitted by astronomers that there actually is such an unexplained secular acceleration of the moon's mean motion.

No passage in Thomson and Tait's "Natural Philosophy" has excited more general interest than that in which Adams is quoted as showing that, *with a certain value for the secular acceleration*, the earth must in a century fall behind a perfect chronometer, set and rated at the beginning of the century, by twenty-two seconds. Unfortunately this passage in the first edition gave an erroneous complexion to Adams's opinion, and being quoted without a statement of the premises, has been used in popular astronomy as an authority for establishing the statement that the earth is actually a false timekeeper to the precise amount specified.

In the second edition (in the editing of which I took part) this passage has been rewritten, and it is shown that Newcomb's estimate of the secular acceleration only gives about one third of the retardation of the earth's rotation, which resulted from Adams's value. The last sentence of the paragraph here runs as follows:—"It is proper to add that Adams lays but little stress on the actual numerical values which have been used in this computation, and is of opinion that the amount of tidal retardation of the earth's rotation is quite uncertain." Thus, in the

opinion of our great physical astronomer, a datum is still wanting for the determination of a limit to geological time, according to Thomson's argument.

However, subject to this uncertainty, with the values used by Adams in his computation, and with the assumption that the rate of tidal friction has remained constant, then a thousand million years ago the earth was rotating twice as fast as at present. In the last edition of the "Natural Philosophy" the argument from these data runs thus:—

"If the consolidation of the earth took place then or earlier, the ellipticity of the upper layers (of the earth's mass) must have been $\frac{1}{230}$ instead of about $\frac{1}{300}$, as it is at present. It must necessarily remain uncertain whether the earth would from time to time adjust itself completely to a figure of equilibrium adapted to the rotation. But it is clear that a want of complete adjustment would leave traces in a preponderance of land in equatorial regions. The existence of large continents and the great effective rigidity of the earth's mass render it improbable that the adjustment, if any, to the appropriate figure of equilibrium would be complete. The fact, then, that the continents are arranged along meridians, rather than in an equatorial belt, affords some degree of proof that the consolidation of the earth took place at a time when the diurnal rotation differed but little from its present value. It is probable, therefore, that the date of consolidation is considerably more recent than a thousand million years ago."

I trust it may not be presumptuous in me to criticise the views of my great master, at whose intuitive perception of truth in physical questions I have often marvelled, but this passage does not even yet seem to me to allow a sufficiently large margin of uncertainty.

It will be observed that the argument reposes on our certainty that the earth possesses rigidity of such a kind as to prevent its accommodation to the figure and arrangement of density appropriate to its rotation. In an interesting discussion on subaerial denudation Croll has concluded that nearly one mile may have been worn off the equator during the past 12,000,000 years, if the rate of denudation all along the equator be equal to that of the basin of the Ganges ("Climate and Time," 1885, p. 336). Now, since the equatorial protuberance of the earth when the ellipticity is $\frac{1}{232}$ is fourteen miles greater than when it is $\frac{1}{300}$, it follows that 170,000,000 years would suffice to wear down the surface to the equilibrium figure. Now let these numbers be halved or largely reduced, and the conclusion remains that denudation would suffice to obliterate external evidence of some early excess of ellipticity.

If such external evidence be gone,[1] we must rely on the incompatibility of the known value of the precessional constant with an ellipticity of internal strata of equal density greater than that appropriate to the actual ellipticity of the surface. Might there not be a considerable excess of internal ellipticity without our being cognisant of the fact astronomically?

And, further, have we any right to feel so confident of the internal structure of the earth as to be able to allege that the earth would not through its whole mass adjust itself almost completely to the equilibrium figure?

Tresca has shown in his admirable memoirs on the flow of solids that when the stresses rise above a certain value the solid becomes plastic, and is brought into what he calls the state of fluidity. I do not know, however, that he determined at what stage the flow ceases when the stresses are gradually diminished. It seems probable, at least, that flow will continue with smaller stresses than were initially necessary to start it. But if this is so, then, when the earth has come to depart both internally and externally from the equilibrium condition, a flow of solid will set in, and will continue until a near approach to the equilibrium condition is attained.

When we consider the abundant geological evidence of the plasticity of rock, and of the repeated elevation and subsidence of large areas on the earth's surface, this view appears to me more probable than Sir William Thomson's.

On the whole, then, I can neither feel the cogency of the argument from tidal friction itself, nor, accepting it, can I place any reliance on the limits which it assigns to geological history.

[1] I find by a rough calculation that [illegible]ths of the land in the northern hemisphere are in the equatorial half of that hemisphere, viz. between 0° and 30° N. lat.; and that [illegible]ths of the land in the southern hemisphere are in the equatorial half of that hemisphere, viz. between 0° and 30° S. lat. Thus for the whole earth, [illegible]ths of all the land lie in the equatorial half of its surface, between 30° N. and S. lat. In this computation the Mediterranean, Caspian, and Black Seas are treated as land.

The second argument concerning geological time is derived from the secular cooling of the earth.

We know in round numbers the rate of increase of temperature, or temperature gradient, in borings and mines, and the conductivity of rock. These data enable us to compute how long ago the surface must have had the temperature of melting rock, and when it must have been too hot for vegetable and animal life.

Sir William Thomson, in his celebrated essay on this subject (republished in Thomson and Tait's "Natural Philosophy," Appendix D), concludes from this argument that "for the last 96,000,000 years the rate of increase of temperature underground has gradually diminished from about $\frac{1}{10}$th to about $\frac{1}{50}$th of a degree Fahrenheit per foot. . . . Is not this, on the whole, in harmony with geological evidence, rightly interpreted? Do not the vast masses of basalt, the general appearances of mountain-ranges, the violent distortions and fractures of strata, *the great prevalence of metamorphic action* (which must have taken place at depths of not many miles, if so much), all agree in demonstrating that the rate of increase of temperature downwards must have been much more rapid, and in rendering it probable that volcanic energy, earthquake shocks, and every kind of so-called plutonic action, have been, on the whole, more abundantly and violently operative in geological antiquity than in the present age?"

Now, while I entirely agree with the general conclusion of Sir William Thomson, it is not unimportant to indicate a possible flaw in the argument. This flaw will only be acknowledged as possible by those who agree with the previous criticism on the argument from tidal friction.

The present argument as to the date of the consolidation of the earth reposes on the hypothesis that the earth is simply a cooling globe, and there are reasons why this may not be the case. The solidification of the earth probably began from the middle and spread to the surface. Now is it not possible, if not probable, that, after a firm crust had been formed, the upper portion still retained some degree of viscosity? If the interior be viscous, some tidal oscillations must take place in it, and, these being subject to friction, heat must be generated in the viscous portion; moreover the diurnal rotation of the earth must be retarded. Some years ago, in a paper on the tides of a spheroid, viscous throughout the whole mass (*Phil. Trans.*, part ii. 1879), I estimated the amount and distribution of the heat generated whilst the planet's rotation is being retarded and the satellite's distance is being increased. It then appeared that on that hypothesis the distribution of the heat must be such that it would only be possible to attribute a very small part of the observed temperature gradient to such a cause. Now, with a more probable internal constitution for the earth in early times, the result might be very different. Suppose, in fact, that it is only those strata which are within some hundreds of miles of the surface which are viscous, whilst the central portion is rigid. Then, when tidal friction does its work the same amount of heat is generated as on the hypothesis of the viscosity of the whole planet, but instead of being distributed throughout the whole mass, and principally towards the middle, it is now to be found in the more superficial layers.

In my paper it is shown that with Thomson's data for the conductivity of rock and the temperature gradient, the annual loss of heat by the earth is 1/260,000,000 part of the earth's kinetic energy of rotation.

Also, if by tidal friction the day is reduced from D_0 hours to D hours, and the moon's distance augmented from Π_0 to Π earth's radii, the energy which has been converted into heat in the process is

$$\left(\frac{D}{D_0}\right)^2 - 1 - 8 \cdot 84 \left(\frac{1}{\Pi} - \frac{1}{\Pi_0}\right) \text{ times the earth's kinetic energy}$$

of rotation.

From these data it results that the heat generated in the lengthening of the day from twenty-three to twenty-four hours is equal to the amount of heat lost by the earth, at its present rate of loss, in 23,000,000 years.

Now if this amount of heat, or any sensible fraction of it, was actually generated within a few hundred miles of the earth's surface, the temperature gradient in the earth must be largely due to it, instead of to the primitive heat of the mass.

Such an hypothesis precludes the assumption that the earth is simply a cooling mass, and would greatly prolong the possible extension of geological time. It must be observed that this view is not acceptable unless we admit that the earth can adjust itself to the equilibrium figure adapted to its rotation.

It seems also worthy of suggestion that our data for the average gradient of temperature may be somewhat fallacious. Recent observations (*Challenger* Expedition) show that the lower stratum of the ocean is occupied by water at near the freezing temperature, whilst the mean annual temperature of the earth's surface, where the borings have been made, must be at least 30° higher. It does not then seem impossible that the mean temperature gradient for the whole earth should differ sensibly from the mean gradient in the borings already made.

The foregoing remarks have not been made with a view of showing Sir William Thomson's argument from the cooling of the earth to be erroneous, but rather to maintain the scientific justice of assigning limits of uncertainty at the very least as wide as those given by him. Prof. Tait ("Recent Advances in Physical Science," 1885) cuts the limit down to 10,000,000 years; he may be right, but the uncertainties of the case are far too great to justify us in accepting such a narrowing of the conclusion.

The third line of argument by which a superior limit is sought for the age of the solar system appears by far the strongest. This argument depends on the amount of radiant energy which can have been given out by the sun.

The amount of work done in the concentration of the sun from a condition of infinite dispersion may be computed with some accuracy, and we have at least a rough idea of the rate of the sun's radiation. From these data Sir William Thomson concludes (Thomson and Tait, "Natural Philosophy," Appendix E):—

"It seems, therefore, on the whole most probable that the sun has not illuminated the earth for 100,000,000 years, and almost certain that he has not done so for 500,000,000 years. As for the future, we may say, with equal certainty, that inhabitants of the earth cannot continue to enjoy the light and heat essential to their life for many million years longer unless sources now unknown to us are prepared in the great storehouse of creation."

This result is based on the value assigned by Pouillet and Herschel to the sun's radiation. Langley has recently made a fresh determination, which exceeds Pouillet's in the proportion of eight to five.[1] With Langley's value Thomson's estimate of time would have to be reduced by the factor five-eighths.

It has been suggested by Croll that the primitive solar nebula may have been hot. This heat must have arisen from the collision of two or more masses; if their relative velocity before collision was that due simply to their mutual attraction, the heat so generated is already counted in the heat generated by the concentration of the sun from a state of infinite dispersion. But if the relative velocity existed otherwise than from their mutual attraction, then the total heat in the sun might exceed that due simply to concentration. Sir William Thomson considers the hypothesis very improbable. The term improbability seems, however, almost to lose its meaning in these speculations, and at least we know by the spectroscope that actual nebulæ do consist of incandescent gases.

In considering these three arguments I have adduced some reasons against the validity of the first argument, and have endeavoured to show that there are elements of uncertainty surrounding the other two; nevertheless they undoubtedly constitute a contribution of the first importance to physical geology. Whilst then we may protest against the precision with which Prof. Tait seeks to deduce results from them, we are fully justified in following Sir William Thomson, who says that "the existing state of things on the earth, life on the earth, all geological history showing continuity of life, must be limited within some such period of past time as 100,000,000 years."

If I have carried you with me in this survey of theories bearing on geological time, you will agree that something has been acquired to our knowledge of the past, but that much more remains still to be determined.

Although speculations as to the future course of science are usually of little avail, yet it seems as likely that meteorology and geology will pass the word of command to cosmical physics as the converse.

At present our knowledge of a definite limit to geological time has so little precision that we should do wrong to summarily reject any theories which appear to demand longer periods of time than those which now appear allowable.

In each branch of science hypothesis forms the nucleus for the aggregation of observation, and as long as facts are assimilated and co ordinated we ought to follow our theory. Thus even if there be some inconsistencies with a neighbouring science we may be justified in still holding to a theory, in the hope that further knowledge may enable us to remove the difficulties. There is no criterion as to what degree of inconsistency should compel us to give up a theory, and it should be borne in mind that many views have been utterly condemned, when later knowledge has only shown us that we were in them only seeing the truth from another side.

[1] Langley (*Ann. Rep. R. A. S.* 1885) estimates that 3 calories per minute are received by a square centimetre at distance unity. This gives for the total annual radiation of the sun $4 \cdot 38 \times 10^{33}$ calories. Thomson gives as Pouillet's estimate 6×10^{3} times the heat required to raise 1 lb. of water 1° Cels., or $2 \cdot 72 \times 10^{33}$ calories.

SECTION B

CHEMICAL SCIENCE

Opening Address by William Crookes, F.R.S., V.P.C.S., President of the Section

A glance over the Presidential addresses delivered before this Section on former occasions will show that the occupiers of this chair have ranged over a fairly wide field. Some of my predecessors have given a general survey of the progress of chemical science during the past year; some, taking up a technological aspect of the subject, have discussed the bearings of chemistry upon our national industries; others, again, have passed in review the various institutions in this country for teaching chemistry; and in yet other cases the speaker has had the opportunity of bringing before the scientific world, for the first time, an account of some important original researches.

On this occasion I venture to ask your attention to a few thoughts on the very foundations of chemistry as a science—on the nature and the probable, or at least possible, origin of the so-called elements. If the views to which I have been led may at first glance appear heretical, I must remind you that in some respects they are shared more or less, as I shall subsequently show, by not a few of the most eminent authorities, and notably by one of my predecessors in this chair, Dr. J. H. Gladstone, F.R.S., to whose brilliant address, delivered in 1883, I must beg to refer you.

Should it not sometimes strike us, chemists of the present day, that after all we are in a position unpleasantly akin to that of our forerunners, the alchemists of the Middle Ages? These necromancers of a time long past did not, indeed, draw so sharp a line as do we between bodies simple and compound; yet their life-task was devoted to the formation of new combinations, and to the attempt to transmute bodies which we commonly consider as simple and ultimate—that is, the metals. In the department of synthesis they achieved very considerable successes; in the transmutation of metals their failure is a matter of history.

But what are we of this so-called nineteenth century doing in our laboratories and our libraries? Too many of us are content to acquire simply what others have already observed and discovered, with an eye directed mainly to medals, certificates, diplomas, and other honours recognised as the fruits of "passing." Others are seeking to turn the determined facts of chemistry to useful purposes; whilst a third class, sometimes not easily distinguished from the second, are daily educing novel organic compounds, or are racking their ingenuity to prepare artificially some product which Nature has hitherto furnished us through the instrumentality of plants and animals. The practical importance of such investigations, and their bearing on the industrial arts and on the purposes and needs of daily life, have been signally manifested during the last half-century.

Still a fourth class of inquirers working at the very confines of our knowledge find themselves, occasionally at least, face to face with a barrier which has hitherto proved impassable, but which must be overthrown, surmounted, or turned, if chemical science is ever to develop into a definite, an organised, unity. This barrier is nothing less than the chemical elements commonly so called, the bodies as yet undecomposed into anything simpler than themselves. There they extend before us, as stretched the wide Atlantic before the gaze of Columbus, mocking, taunting, and murmuring strange riddles which no man yet has been able to solve.

The first riddle, then, which we encounter in chemistry is, "What are the elements?" Of the attempts hitherto made to

define or explain an element, none satisfy the demands of the human intellect. The text-books tell us that an element is "a body which has not been decomposed"; that it is "a something to which we can add, but from which we can take away nothing," or, "a body which increases in weight with every chemical change." Such definitions are doubly unsatisfactory: they are provisional, and may cease to-morrow to be applicable in any given case. They take their stand, not on any attribute of the things to be defined, but on the limitations of human power; they are confessions of intellectual impotence.

Just as to Columbus long philosophic meditation led him to the fixed belief of the existence of a yet untrodden world beyond that waste of Atlantic waters, so to our most keen-eyed chemists, physicists, and philosophers a variety of phenomena suggest the conviction that the elements of ordinary assumption are not the ultimate boundary in this direction of the knowledge which man may hope to attain. Well do I remember, soon after I had obtained evidence of the distinct nature of thallium, that Faraday said to me—"To discover a new element is a very fine thing, but if you could decompose an element and tell us what it is made of—that would be a discovery indeed worth making." And this was no new speculation of Faraday's, for in one of his early lectures he remarked—"At present we begin to feel impatient, and to wish for a new state of chemical elements. For a time the desire was to add to the metals, now we wish to diminish their number. . . . To decompose the metals, then, to re-form them, to change them from one to another, and to realise the once absurd notion of transmutation, are the problems now given to the chemist for solution."

Mr. Herbert Spencer, in his hypothesis of the constitution of matter, says: "All material substances are divisible into so-called elementary substances composed of molecular particles of the same nature as themselves; but these molecular particles are complicated structures consisting of congregations of truly elementary atoms, identical in nature and differing only in position, arrangement, motion, &c., and the molecules or chemical atoms are produced from the true or physical atoms by processes of evolution under conditions which chemistry has not yet been able to reproduce."

Mr. Norman Lockyer has shown, I think on good evidence, that in the heavenly bodies of the highest temperature a large number of our reputed elements are dissociated, or, as it would perhaps be better to say, have never been formed. Mr. Lockyer holds that "the temperature of the sun and the electric arc is high enough to dissociate some of the so-called chemical elements, and give us a glimpse of the spectra of their bases"; and he likewise says that "a terrestrial element is an exceedingly complicated thing that is broken up into simpler things at the temperature of the sun, and some of these things exist in some sun-spots, while other constituents exist in others."

The late Sir Benjamin Brodie, in a lecture on "Ideal Chemistry" delivered before the Chemical Society in 1867, goes even further than this. He says:—"We may conceive that, in remote time or in remote space, there did exist formerly, or possibly do exist now, certain simpler forms of matter than we find on the surface of our globe—α, χ, ξ, ν, and so on. . . . We may consider that in remote ages the temperature of matter was much higher than it is now, and that these other things existed then in the state of perfect gases—separate existences—uncombined. . . . We may then conceive that the temperature began to fall, and these things to combine with one another and to enter into new forms of existence, appropriate to the circumstances in which they were placed. . . . We may further consider that, as the temperature went on falling, certain forms of matter became more permanent and more stable, to the exclusion of other forms. . . . We may conceive of this process of the lowering of the temperature going on, so that these substances, when once formed, could never be decomposed—in fact, that the resolution of these bodies into their component elements could never occur again. You would then have something of our present system of things. . . .

"Now this is not purely an imagination, for when we look upon the surface of our globe we have actual evidence of similar changes in Nature. . . . When we look at some of the facts which have been revealed to us by the extraordinary analyses which have been made of the matter of distant worlds and nebulæ, by means of the spectroscope, it does not seem incredible to me that there may even be evidence, some day, of the independent existence of such things as χ and ν."

In his Burnett Lectures "On Light as a Means of Investigation," Prof. Stokes, speaking of a line in the spectrum of the nebulæ, says:—"It may possibly indicate some form of matter more elementary than any we know on earth. There seems no *a priori* improbability in such a supposition so great as to lead us at once to reject it. Chemists have long speculated on the so-called elements, or many of them, being merely very stable compounds of elements of a higher order, or even perhaps of a single kind of matter."

In 1868 Graham wrote of Sir W. Thomson's vortex-ring theory as enlivening "matter into an individual existence and constituting it a distinct substance or element."

From these passages, which might easily be multiplied, it plainly appears that the notion—not necessarily of the decomposability, but at any rate of the complexity, of our supposed elements—is, so to speak, in the air of science, waiting to take a further and more definite development. It is important to keep before men's minds the idea of the genesis of the elements; this gives some form to our conceptions, and accustoms the mind to look for some physical production of atoms. It is still more important, too, to keep in view the great probability that there exist in Nature laboratories where atoms are formed, and laboratories where atoms cease to be. We are on the track and are not daunted, and fain would we enter the mysterious region which ignorance tickets "Unknown." It is for us to strive to unravel the secret composition even of the so-called elements—to undauntedly persevere—and "still bear up right onward."

If we adopt the easy-going assumption that the elements, whether self-existent or created, are absolutely and primordially distinct; that they existed as we now find them prior to the origin of stars and their attendant planets, constituting, in fact, the primal "fire-mist," we are little, if any, the wiser. We look at their number and at their distinctive properties, and we ask, Are all these points accidental or determinate? In other words, might there as well have been only 7, or 700, or 7000 absolutely distinct elements as the 70 (in round numbers) which we now commonly recognise? The number of the elements does not, indeed, commend itself to our reason from any *a priori* or extraneous considerations. Might their properties have conceivably differed from those which we actually observe? Are they formed by a "fortuitous concatenation," or do they constitute together a definite whole, in which each has its proper part to play, and from which none could be extruded without leaving a recognisable deficiency?

If their peculiarities were accidental, it would scarcely be possible for the elements to display those mutual relations which we find brought into such prominent light and order in the periodic classification of Newlands, Mendeléeff, and Meyer. Has not the relation between the atomic weights of the three halogens, chlorine, bromine, and iodine, and their serially varying properties, physical and chemical, been worn nearly threadbare? And the same with the calcium and the sulphur groups? Surely the probability of such relations existing among some seventy bodies which had come into fortuitous existence would prove to be vanishingly small!

We ask whether these elements may not have been evolved from some few antecedent forms of matter—or possibly from only one such—just as it is now held that all the innumerable variations of plants and animals have been developed from fewer and earlier forms of organic life? As Dr. Gladstone well puts it, they "have been built up from one another, according to some general plan." This building up, or evolution, is above all things not fortuitous: the variation and development which we recognise in the universe run along certain fixed lines which have been preconceived and foreordained. To the careless and hasty eye, design and evolution seem antagonistic; the more careful inquirer sees that evolution, steadily proceeding along an ascending scale of excellence, is the strongest argument in favour of a preconceived plan.

The array of the elements cannot fail to remind us of the general aspect of the organic world. In both cases we see certain groups well filled up, even crowded with forms having among themselves but little specific difference. On the other hand, in both, other forms stand widely isolated. Both display species that are common and species that are rare; both have groups widely distributed—it might be said cosmopolitan, and other groups of very restricted occurrence. Among animals I may mention as instances the Monotremata of Australia and New Guinea, and among the elements the metals of the so-called rare earths.

Now as these facts in the distribution of organic forms are generally considered by biological experts to rank among the weightiest evidences in favour of the origin of species by a process of evolution, it seems natural, in this case as in the other, to view existing elements not as primordial but as the gradual outcome of a process of development, possibly even of a "struggle for existence." Bodies not in harmony with the present general conditions have disappeared or perhaps have never existed. Others—the asteroids among the elements—have come into being and have survived, but only on a limited scale; whilst a third class are abundant because surrounding conditions have been favourable to their formation and preservation.

The analogy here suggested between elements and organisms is, indeed, not the closest, and must not be pushed too far. From the nature of the case there cannot occur in the elements a difference corresponding to the difference between living and fossil organic forms. The "great stone book" can tell us nothing of extinct elements. Nor would I for a moment suggest that any one of our present elements, however rare, is like a rare animal or plant in process of extinction; that any new element is in the course of formation, or that the properties of existing elements are gradually undergoing modification. All such changes must have been confined to that period so remote as not to be grasped by the imagination, when our earth, or rather the matter of which it consists, was in a state very different from its present condition. The epoch of elemental development is decidedly over, and I may observe that in the opinion of not a few biologists the epoch of organic development is verging upon its close.

Making, however, every allowance for these distinctions, if evolution be a cosmic law, manifest in heavenly bodies, in organic individuals, and in organic species, we shall in all probability recognise it, though under especial aspects, in those elements of which stars and organisms are in the last resort composed.

Is there then, in the first place, any direct evidence of the transmutation of any supposed "element" of our existing list into another, or of its resolution into anything simpler?

To this question I am obliged to reply in the negative.

I doubt whether any chemist here present could suggest a process which would hold out a reasonable prospect of dissociating any of our accepted simple bodies. The highest temperatures and the most powerful electric currents at our disposal have been tried, and tried in vain. At one time there seemed a possibility at least that the interesting researches of Prof. Victor Meyer might show the two higher members of the halogen group, bromine and iodine, as entering upon the path of dissociation. These hopes have not been fulfilled. It may be said, in the general opinion of the most eminent and judicious chemists, that none of the phenomena thus elicited prove that even an approach has been made to the object in view.

Even if we leave our artificial laboratories and seek an escape from the difficulty by observing the processes of the great laboratories of Nature, we feel no sufficiently firm ground.

We find ourselves thus driven to indirect evidence—to that which we may glean from the mutual relations of the elementary bodies. Such evidence of great value is by no means lacking, and to this I now beg to direct attention. First, we may consider the conclusion arrived at by Herschel, and pursued by Clerk-Maxwell, that atoms bear the impress of manufactured articles. Let us look a little more closely at this view. A manufactured article may well be supposed to involve a manufacturer. But it does something more: it implies certainly a raw material, and probably, though not certainly, the existence of by-products, residues, paraleipomena. What or where is here the raw material? Can we detect any form of matter which bears to the chemical elements a relation like that of a raw material to the finished product, like that, say, of coal-tar to alizarin? Or can we recognise any elementary bodies which seem like waste or refuse? Or are all the elements, according to the common view, co-equals? To these questions no direct answer is as yet forthcoming.

And this leads us up to an hypothesis which, if capable of full demonstration, would show us that the accepted elements are not co-equal, but have been formed by a process of expansion or evolution. I refer to the well-known hypothesis of Prout, which regards the atomic weights of the elements as multiples, by a series of whole numbers, of unity = the atomic weight of hydrogen. Every one is aware that the recent more accurate determinations of the atomic weights of different elements do not by any means bring them into close harmony with the values which Prout's law would require. Still, in no small number of cases the actual atomic weights approach so closely to those which the hypothesis demands, that we can scarcely regard the coincidence as accidental. Accordingly, not a few chemists of admitted eminence consider that we have here an expression of the truth, masked by some residual or collateral phenomena which we have not yet succeeded in eliminating.

The original calculations on which the most accurate numbers for the atomic weights are founded, have recently been recalculated by Mr. F. W. Clarke. In his concluding remarks, speaking of Prout's law, Mr. Clarke says that "none of the seeming exceptions are inexplicable. In short, admitting half-multiples as legitimate, it is more probable that the few apparent exceptions are due to undetected constant errors than that the great number of close agreements should be merely accidental. I began this re-calculation of the atomic weights with a strong prejudice against Prout's hypothesis, but the facts as they came before me have forced me to give it a very respectful consideration."

But if the evidence in favour of Prout's hypothesis in its original guise is deemed insufficient, may not Mr. Clarke's suggestion of half-multiples place it upon an entirely new basis? Suppose that the unit of the scale, the body whose atomic weight if multiplied by a series of whole numbers gives the atomic weights of the remaining elements, is not hydrogen, but some element of still lower atomic weight? We are here at once reminded of helium—an element purely hypothetical as far as our earth is concerned, but supposed by many authorities, on the faith of spectroscopic observations, to exist in the sun and in other stellar bodies. Most solar eruptions present merely the characteristic lines of hydrogen, C, F, and H, and along with them one particular line which at first was classed in the sodium group, but which is a little more refrangible, and is designated by the symbol D_3. According to Mr. Norman Lockyer and the late Father Secchi, this ray undergoes modifications not comparable to those affecting other rays of the chromosphere. In the corresponding region of the spectrum no dark ray has been observed. That the accompanying lines, C, F, and H, pertain to hydrogen is evident; and as D_3 has never been obtained in any other spectrum it is supposed to belong to a body foreign to our earth, though existing in abundance in the chromosphere of the sun. To this hypothetical body the name helium is assigned.

In an able memoir on this subject read before the Academy of Brussels, the Abbé E. Spée shows that, if helium exists, it enjoys two very remarkable properties. Its spectrum consists of a single ray, and its vapour possesses no absorbent power. The simple single ray, though I believe unexampled, is by no means an impossible phenomenon, and indicates a remarkable simplicity of molecular constitution. The non-absorbent property of its vapour seems to be a serious objection to a general physical law. Prof. Tyndall has demonstrated that the absorptive power increases with the complexity of molecular structure, and hence he draws the conclusion that the simpler the molecule the feebler the absorption. This conclusion the Abbé Spée regards as perfectly legitimate; but it neither explains nor even necessitates the absence of *all* absorptive power.

Granting that helium exists, all analogy points to its atomic weight being below that of hydrogen. Here, then, we may have the very element with atomic weight half that of hydrogen, required by Mr. Clarke as the basis of Prout's law.

But a more important piece of evidence for the compound nature of the chemical elements has yet to be considered. Many chemists must have been struck with certain peculiarities in the occurrence of the elements in the earth's crust; it is a stale remark that we do not find them evenly distributed throughout the globe. Nor are they associated in accordance with their specific gravities; the lighter elements placed on or near the surface, and the heavier ones following serially deeper and deeper. Neither can we trace any distinct relation between local climate and mineral distribution. And by no means can we say that elements are always or chiefly associated in Nature in the order of their so-called chemical affinities; those which have a strong tendency to form with each other definite chemical combinations being found together, whilst those which have little or no such tendency exist apart. We certainly find calcium as

carbonate and sulphate, sodium as chloride, silver and lead as sulphides; but why do we find certain groups of elements with little affinity for each other yet existing in juxtaposition or commixture? The members of some of these groups are far from plentiful, not generally or widely diffused, and certainly they are not easy to separate.

As instances of such grouping we may mention:—

(1) Nickel and cobalt, of which it may be said that had their compounds been colourless, they would have been long regarded as identical, and possibly even yet would not have been separated.

(2) The two groups of platinum metals.

(3) The so-called "rare earths," occurring in gadolinite, samarskite, &c., and evidently becoming more numerous the more closely they are examined.

Certain questions here suggest themselves:—Is the series of these elements like a staircase or like an inclined plane? Will they, the more closely they are scrutinised, be found to fade away the more gradually the one into the other? Further, will a mixture hitherto held to be simple, like (*e.g.*) didymium, be capable of being split up in one direction only, or in several? I have been led to ask this last question because I have separated from didymium bodies which seem to agree neither with the praseodymium and neodymium of Dr. Auer von Welsbach, nor with the components detected by M. de Boisbaudran and M. Demarçay.

Why, then, are these respective elements so closely associated? What agency has brought them together?

An eminent physicist evades the difficulty by suggesting that their joint occurrence is simply an instance of the working of the familiar principle, "Birds of a feather flock together." In their chemical and physical attributes these rare earths are so closely similar, that they may be regarded as substantially identical in all the circumstances of solution and precipitation to which they may have been exposed during geological ages.

But do we, in point of fact, recognise any such agency at work in Nature? Is there any power which regularly and systematically sorts out the different kinds of matter from promiscuous heaps, conveying like to like and separating unlike from unlike? I must confess that I fail to trace any such distributive agency, nor, indeed, do I feel able to form any distinct conception of its nature.

I must here remark that coral worms in some cases do effect a separation of certain kinds of matter. Thus a *Gorgonia* of the species of *Melithæa*, and *Mussa sinuosa*, undoubtedly eliminate from sea-water not merely lime, but even yttria; and other recent corals, *Pocillopora damicornis*, and a *Symphyllia* close to the yttria-secreting *Mussa*, separate samaria from sea-water. Sea-weeds and aquatic mollusks contain a larger proportion of iodide and bromine than the waters which they inhabit, and may thus be said to separate out these elements from the chlorine with which they are mingled.

But if we examine these cases of elimination we see that they are limited in their scope. They extend only to substances existing in solution of which there is a fresh supply always at hand, and which are capable of entering into the animal or vegetable economy. Again, the elimination of iodine and bromine, effected as just described, is of a very imperfect character, and, when such water-plants and animals die and decay, their constituents will be again distributed in the water.

We cannot well consider that nickel and cobalt have been deposited in admixture by organic agency, nor yet the groups iridium, osmium, and platinum—ruthenium, rhodium, and palladium.

Since the earthy metals to which I have referred—such as yttrium, samarium, holmium, erbium, thulium, ytterbium, &c.—are very rare, the probability of their ever having been brought together in some few uncommon minerals discovered only in a few localities must be regarded as trifling indeed, if we suppose that these metals had at any time been widely diffused in a state of great dilution with other matter. The features which we have just recognised in these earths seem to point to their formation severally from some common material placed in conditions in each case nearly identical. The case is strengthened by a consideration of the other groups of elements, also similar in properties, having little affinity for each other and occurring in admixture; either all or at least some of the elements concerned being moreover decidedly rare. Thus we have nickel and cobalt not plentiful or widely distributed; cobalt, perhaps, never found absolutely free from nickel, and *vice versâ*. We have also the two platinum groups, where very similar features prevail.

A weighty argument in favour of the compound nature of the elements is that drawn from a consideration of the compound radicals, or, as they might be called, pseudo-elements. Their similarity with the accepted elements is perfectly familiar to all chemists. If, for example, we suppose that in some age or in some country men of science were cognisant of the existence and of the behaviour of cyanogen, but had not succeeded in resolving it into its constituents, nothing, surely, would prevent their viewing it as an element, and assigning it a place with the halogens. It may fairly be held that if a body which we know to be compound can be found playing the part of an element, this fact lends a certain plausibility to the supposition that the elements also are not absolutely simple. This line of thought, or at least one closely approximating to it, was worked out by Dr. Carnelley in a paper read before this Association at its last meeting. From a comparison of the physical properties of inorganic with those of organic compounds, Dr. Carnelley concludes that "*the elements, as a whole, are analogous to the hydrocarbon radicals.*" This conclusion, if true, he adds, should lead to the further inference that the so-called elements are not truly elementary, being made up of at least two absolute elements, named provisionally A and B. Hence, he argues, it should be possible to build up a series of compounds of these two primary elements which would correspond to what we now call elements. Such an arrangement, to be admissible, would have to fulfil certain conditions:—The secondary elements thus generated from A and B must exhibit the phenomena of periodicity, and the series would have to form octaves: the entire system is bound to display some feature corresponding to the "odd and even series" of Mendeléeff's classification; the atomic weights must increase across the system from the first to the seventh group—that is, from the positive to the negative end of each series; the atomicity would have to increase from the first to the middle group, and then either increase or decrease to the seventh group; some feature should appear corresponding to the eighth group; and, lastly, the atomic weights in such a system ought to agree with the atomic weights as experimentally determined.

This last condition Dr. Carnelley rightly regards as the most crucial, and he finds his arrangement gives atomic weights which in a majority of instances coincide approximately with the actual atomic weights. Thus out of a total of sixty-one elements whose atomic weights have been determined with at least approximate accuracy, and whose places in the periodic system is not disputed, twenty-seven agree almost exactly with the actual numbers, whilst nineteen others are not more than one unit astray.

For a detailed consideration of the conclusions which follow from Dr. Carnelley's views I must refer to his paper as read at our last meeting. Two points bear more especially upon the subject now under consideration—that is, if this speculation on the genesis of the elements is well-founded. First, the existence of elements of identical atomic weights, isomeric with each other, would be possible; as such, Dr. Carnelley mentions respectively nickel and cobalt (now found to have slightly different atomic weights), rhodium and ruthenium, osmium and iridium, and the metals of some of the rare earths. Secondly, in Dr. Carnelley's scheme all the chemical elements save hydrogen are supposed to be composed of two simpler elements, $A = 12$ and $B = -2$. Of these he regards A as a tetrad identical with carbon, and B as a monad of negative weight—perhaps the ethereal fluid of space.

Dr. Carnelley's three primary elements therefore are carbon, hydrogen, and the ether.

Starting from the supposition that pristine matter was once in an intensely heated condition, and that it has reached its present state by a process of free cooling, Dr. E. J. Mills suggests that the elements, as we now have them, are the result of successive polymerisations. Dr. Mills reminds us that chemical substances in the process of cooling naturally increase in density, and, if such increase be measured as a function of time or of temperature, we sometimes observe that there are critical points corresponding to the formation of new and well-defined substances. In this manner ordinary phosphorus is converted into the red variety, I is transformed into I_2, S_2 becomes S_6, and NO_2 N_2O_4. Among organic bodies styrol, in like manner, according to Dr.

Mills, is converted into metastyrol, aldehyd into paraldehyd, the cyanates into cyanurates, and turpentine into metaterebenthene. At the critical points above referred to heat is liberated in especial abundance, and the bodies thus formed are known as polymers. If we could gradually cool down substances through a vast range of temperature, we should then probably discover a much greater number of such critical points, or points of multiple proportion, than we have been able to discover experimentally.

The heat given out in the act of polymerisation naturally reverses to some extent the polymerisation itself, and so causes a partial return to the previous condition of things. This forward and backward movement, several times repeated, constitutes "periodicity." Dr. Mills regards variable stars as instances, now in evidence, of the genesis of elementary bodies.

From a study of the classification of the elements, Dr. Mills is of opinion that the only known polymers of the primitive matter are arsenic, antimony, and perhaps erbium and osmium; whilst zirconium, ruthenium, samarium, and platinum approximate to the positions of other polymers. Hence, from this genetic view, these elements may be described as products of successive polymerisations.

I must now call attention to a method of illustrating the periodic law, proposed by my friend Prof. Emerson Reynolds, of the University of Dublin, which will here assist us. Prof. Reynolds points out that in each period the general properties of the elements vary from one to another with approximate regularity until we reach the seventh member, which is in more or less striking contrast with the first element of the same period, as well as with the first of the next. Thus chlorine, the seventh member of Mendeléeff's third period, contrasts sharply both with sodium, the first member of the same series, and with potassium, the first member of the next series, whilst, on the other hand, sodium and potassium are closely analogous. The six elements whose atomic weights intervene between sodium and potassium vary in properties, step by step, until chlorine, the contrast to sodium, is reached. But from chlorine to potassium, the analogue of sodium, there is a change in properties *per saltum*. Further, such alternations of gradual and abrupt transitions are observed as the atomic weights increase. If we thus recognise a contrast in properties—more or less decided—between the first and the last members of each series, we can scarcely help admitting the existence of a point of mean variation within each system. In general, the *fourth* element of each series possesses the properties we might expect a transition-element to exhibit. If we examine a particular period—for instance, that one whose meso-element is silicon, we note:—*First*, that the three elements of lower atomic weight than silicon, viz. sodium, magnesium, and aluminium, are distinctly *electro-positive* in character, while those of higher atomic weight, viz. phosphorus, sulphur, and chlorine, are as distinctly *electro-negative*. Throughout the best-known periods this remarkable subdivision is observable, although, as might be anticipated, the differences become less strongly marked as the atomic weights increase. *Secondly*, that the members above and below the meso-element fall into pairs of elements, which, while exhibiting certain analogies, are generally in more or less direct chemical contrast. Thus, in the silicon period we have—

$$\begin{array}{cc} \multicolumn{2}{c}{\mathrm{Si}^{\mathrm{iv}}} \\ +\mathrm{Al}''' & \mathrm{P}'''- \\ +\mathrm{Mg}'' & \mathrm{S}''- \\ +\mathrm{Na}' & \mathrm{Cl}'- \end{array}$$

This divison also happens, in many cases, to coincide with some characteristic valence of the contrasted elements. It is noteworthy, however, that the members on the electro-negative side exhibit the most marked tendency to vibration in atom-fixing power, so that valence alone is an untrustworthy guide to the probable position of an element in a period.

Thus for the purpose of graphic translation Prof. Reynolds considers that the fourth member of a period—silicon, for example—may be placed at the apex of a symmetrical curve, which shall represent, for that particular period, the direction in which the properties of the series of elements vary with rising atomic weights.

In the drawing before you (Fig. 1) I have modified Prof. Reynolds's diagram in one or two points. I have turned it the reverse way, as it is more convenient to start from the top and proceed downwards. I have represented the pendulous swing as gradually declining in amplitude, according to a mathematical law, and I have introduced another half-swing of the pendulum between cerium and lead, which not only renders the oscillations more symmetrical, but brings gold, mercury, thallium, lead, and bismuth on the side where they are in complete harmony with members of foregoing groups, instead of being out of harmony with them. This modification has another advantage, inasmuch as it leaves many gaps to be hereafter filled in with new elements just when the development of research is beginning to demand room for such expansion.

I do not, however, wish to infer that the gaps in Mendeléeff's table, and in this graphic representation of it, necessarily mean that there are elements actually existing to fill up the gaps; these gaps may only mean that at the birth of the elements there was an easy potentiality of the formation of an element which would fit into the place.

Following the curve from hydrogen downwards we find that the elements forming Mendeléeff's eighth group are to be found near three of the ten nodal points. These bodies are "interperiodic," both because their atomic weights exclude them from the small periods into which the other elements fall, and because their chemical relations with certain members of the adjacent periods show that they are probably interperiodic in the sense of being transitional.

This eighth group is divided into the three triplets—iron, nickel, and cobalt; rhodium, ruthenium, and palladium; iridium, osmium, and platinum. The members of each triplet have often been regarded as modifications of one single form of matter.

Notice how accurately the series of like bodies fits into this scheme. Beginning at the top, run the eye down analogous positions in each oscillation, taking either the electro-positive or electro-negative swings:—

N	Be	Li	Na	Mg	Al	Si	P	S	Cl	C
V	Ca	K	Cu	Zn	Ga	Ge	As	Se	Br	Ti
Nb	Sr	Rb	Ag	Cd	In	Sn	Sb	Te	I	Zr
—	Ba	Cs	—	—	—	—	—	—	—	—
Ta			Au	Hg	Tl	Pb	Bi			

Notice, also, how orderly the metals discovered by spectrum analysis fit in their places—gallium, indium, and thallium.

The symmetry of nearly all this series proclaims at once that we are working in the right direction. We can also learn much from the anomalies here visible. Look at the places marked with a circle: didymium, samarium, holmium, erbium, ytterbium, and thulium. Didymium cannot follow in order after the triad nitrogen, vanadium, columbium; nor erbium follow phosphorus, arsenic, antimony; nor thulium follow chlorine, bromine, iodine; nor ytterbium follow potassium, rubidium, cæsium. The inference to be drawn is that these bodies are out of place, owing to their atomic weights not having been correctly determined—an inference which is strengthened by the knowledge that the elementary character of some of these bodies is more than doubtful, whilst the chemical attributes of most of them are unknown.

The more I study the arrangement of this zigzag curve the more I am convinced that he who grasps the key will be permitted to unlock some of the deepest mysteries of creation. Let us imagine if it is possible to get a glimpse of a few of the secrets here hidden. Let us picture the very beginnings of time, before geological ages, before the earth was thrown off from the central nucleus of molten fluid, before even the sun himself had consolidated from the original *protyle*.[1] Let us still imagine that at this primal stage all was in an ultra-gaseous state, at a temperature inconceivably hotter[2] than anything now existing in the visible universe; so high, indeed, that the chemical atoms could not yet have been formed, being still far above their dissociation-point. In so far as *protyle* is capable of radiating or reflecting light, this vast sea of incandescent mist, to an astronomer in a distant star, might have appeared as a nebula, showing in the spectroscope a few isolated lines, forecasts of hydrogen, carbon, and nitrogen spectra.

[1] We require a word, analogous to protoplasm, to express the idea of the original primal matter existing before the evolution of the chemical elements. The word I have ventured to use for this purpose is compounded of προ (*earlier than*) and ὕλη (*the stuff of which things are made*). The word is scarcely a new coinage, for 600 years ago Roger Bacon wrote in his "De Arte Chymiæ":—"The elements are made out of ὕλη, and every element is converted into the nature of another element."

[2] I am constrained to use words expressive of high temperature; but I confess I am unable clearly to associate with *protyle* the idea of hot or cold. *Temperature, radiation*, and *free cooling* seem to require the periodic motions that take place in the chemical atoms; and the introduction of centres of periodic motion into *protyle* would constitute its being so far changed into chemical atoms.

But in course of time some process akin to cooling, probably internal, reduces the temperature of the cosmic *protyle* to a point at which the first step in granulation takes place; matter as we know it comes into existence, and atoms are formed. As soon as an atom is formed out of *protyle* it is a store of energy, potential (from its tendency to coalesce with other atoms by gravitation or chemically) and kinetic (from its internal motions). To obtain this energy, the neighbouring *protyle* must be refrigerated by it,[1] and thereby the subsequent formation of other atoms will be accelerated. But with atomic matter the various forms of energy which require matter to render them evident begin to act; and, amongst others, that form of energy which has for one of its factors what we now call *atomic weight*. Let us assume that the elementary *protyle* contains within itself the potentiality of every possible combining proportion or atomic weight. Let it be granted that the whole of our known elements were not at this epoch simultaneously created. The easiest formed element, the one most nearly allied to the *protyle*

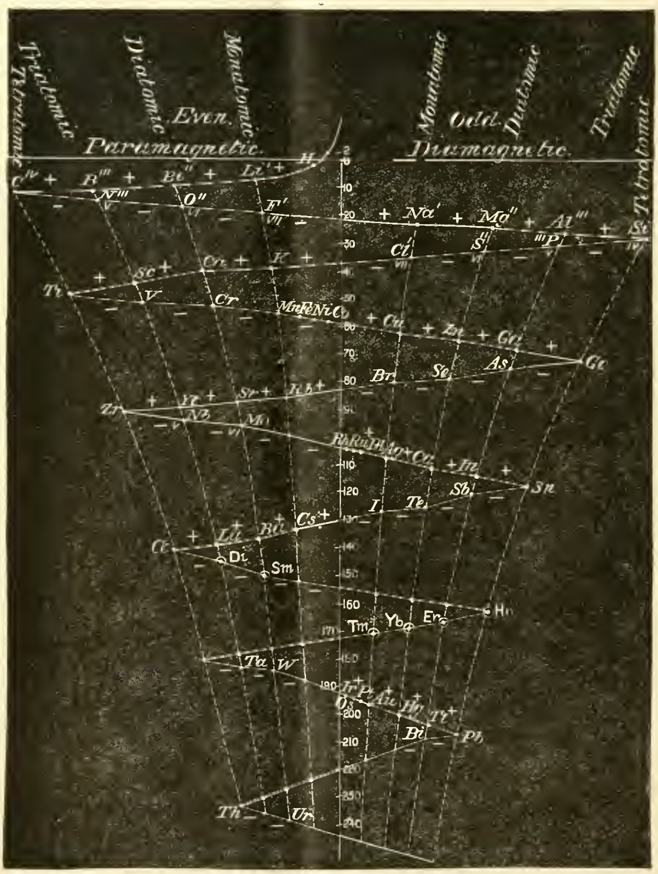

FIG. 1.

in simplicity, is first born. Hydrogen — or shall we say helium?—of all the known elements the one of simplest structure and lowest atomic weight, is the first to come into being. For some time hydrogen would be the only form of matter (as we now know it) in existence, and between hydrogen and the next formed element there would be a considerable gap in time, during the latter part of which the element next in order of simplicity would be slowly approaching its birth-point: pending this period we may suppose that the evolutionary process which soon was to determine the birth of a new element, would also determine its atomic weight, its affinities, and its chemical position.

In the original genesis, the longer the time occupied in that portion of the cooling down during which the hardening of the *protyle* into atoms took place the more sharply defined would be the resulting elements; and, on the other hand, with more irregularity in the original cooling we should have a nearer approach to the state of the elemental family such as we know it at present

[1] I am indebted to my friend, G. Johnstone Stoney, F.R.S., for the idea here put forward, as well as for other valuable suggestions and criticisms on some of the theoretical questions here treated of.

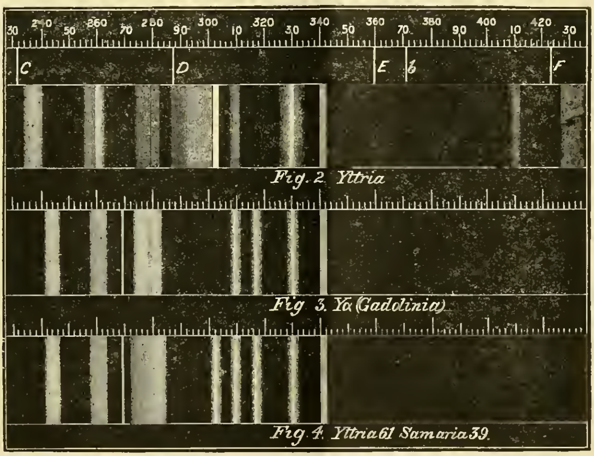
In this way it is conceivable that the succesion of events which gave us such groups as platinum, osmium, and iridium—palladium, ruthenium, and rhodium—iron, nickel, and cobalt, if the operation of genesis had been greatly more prolonged, would have resulted in the birth of only one element of these groups. It is also probable that, by a much more rapid rate of cooling, elements would originate even more closely related than are nickel and cobalt, and thus we should have formed the nearly allied elements of the cerium, yttrium, and similar groups; in fact, the minerals of the class of samarskite and gadolinite may be regarded as the cosmical lumber-room where the elements in a state of arrested development—the unconnected missing links of inorganic Darwinism—are finally aggregated.

I have said that the original *protyle* contained within itself the potentiality of all possible atomic weights. It may well be questioned whether there is an absolute uniformity in the mass of every ultimate atom of the same chemical element. Probably our atomic weights merely represent a mean value around which the actual atomic weights of the atoms vary within certain narrow limits.

Each well-defined element represents a platform of stability connected by ladders of unstable bodies. In the first accreting together of the primitive stuff the smallest atoms would form, then these would join together to form larger groups, the gulf across from one stage to another would be gradually bridged over, and the stable element appropriate to that stage would absorb, as it were, the unstable rungs of the ladder which led up to it. I conceive, therefore, that when we say the atomic weight of, for instance, calcium is 40, we really express the fact that, while the majority of calcium atoms have an actual atomic weight of 40, there are not a few which are represented by 39 or 41, a less number by 38 or 42, and so on. We are here reminded of Newton's "old worn particles."

Is it not possible, or even feasible, that these heavier and lighter atoms may have been in some cases subsequently sorted out by a process resembling chemical fractionation? This sorting out may have taken place in part while atomic matter was condensing from the primal state of intense ignition, but also it may have been partly effected in geological ages by successive solutions and re-precipitations of the various earths.

This may seem an audacious speculation, but I do not think it is beyond the power of chemistry to test its feasibility. An investigation on which I have been occupied for several years has yielded results which to me appear apposite to the question, and I therefore beg permission here to allude briefly to some of the



Figs. 2–4.

results, reserving details for a subsequent communication to the Section.

My work has been with the earths present in samarskite and gadolinite, separating them by systematic fractionation. Chemical fractionation, on which I hope to say more on another occasion, is very similar to the formation of a spectrum with a wide slit and a succession of shallow prisms. The centre portion remains unchanged for a long time, and the only approach to purity at first is at the two ends, while a considerable series of operations is needed to produce an appreciable change in the centre. The groups of didymium and yttrium earths are those which have chiefly occupied my attention. On comparing these rare earths we are at once struck with the close mutual similarity, verging almost into identity, of the members of the same group.

The phosphorescent spectra of these earths when their anhydrous sulphates are submitted to the induction discharge *in vacuo* are extremely complicated, and change in their details in a puzzling manner. For many years I have been persistently groping on in almost hopeless endeavour to get a clue to the meaning I felt convinced was locked up in these systems of bands and lines. It was impossible to divest myself of the conviction that I was looking at a series of autograph inscriptions from the molecular world, evidently of intense interest, but written in a strange and baffling tongue. All attempts to decipher the mysterious signs were, however, for a long time, fruitless. I required a Rosetta stone.

Down to a date comparatively recent nothing was more firmly fixed in my mind than the notion that yttria was the oxide of a simple body, and that its phosphorescent spectrum gave a definite system of coloured bands, such as you see in the drawing before you (Fig. 2). Broadly speaking, there is a deep red band, a red band, a very luminous citron-coloured band, a pair of greenish-blue bands, and a blue band. It is true these bands varied slightly in relative intensities and in sharpness with almost every sample of yttria I examined; but the general character of the spectrum remained unchanged, and I had got into the way of looking upon this spectrum as characteristic of yttria: all the bands being visible when the earth was present in quantity, whilst only the strongest band of all—the citron band—was visible when traces, such as millionths, were present. But that the whole system of bands spelled yttria and nothing but yttria I was firmly convinced.

During the later fractionations of the yttria earths, and the continued observations of their spectra, certain suspicions which had troubled me for some time assumed consistent form. The bands which hitherto I had thought belonged to yttria began to

vary in intensity among themselves, and continued fractionation increased the differences first observed. Whilst I was in this state of doubt and uncertainty, and only beginning to see my way towards arranging into a consistent whole the facts daily coming to light, help came from an unexpected quarter. M. de Marignac, with whom I had been for some time in correspondence, kindly sent me a small specimen of the earth which he had discovered and provisionally named $Y\alpha$. In the radiant-matter tube this earth gave a bright spectrum like the one in the diagram before you (Fig. 3). The spectrum above it (Fig. 2) is that ascribed to yttria. Look at the two. Omitting minor details, $Y\alpha$ is yttria with the chief characteristic band—the citron band—left out, and with the double green band of samaria added to it. Now look at Fig. 4, which represents the spectrum of a mixture of 61 parts of yttria and 39 parts of samaria. It is identical almost to its minutest detail with the spectrum of $Y\alpha$, with this not unimportant difference—the citron band is as prominent as any other line. $Y\alpha$ consists, therefore, of samaria with the greenish blue of yttria and some of the other yttria bands added to it.

I may aptly call the $Y\alpha$ spectrum my Rosetta stone. It threw a flood of light on all the obscurities and contradictions I had found so plentiful, and showed me that a much wider law than the one I had been working upon was the true law governing the occurrence of these obscure phenomena. For what does the spectrum of $Y\alpha$ show? It proves that what I had hitherto thought was one of the chief bands in the yttria spectrum—the citron band—could be entirely removed, whilst another characteristic group—the double green of yttria—could also be separated from the citron.

It would exceed legitimate limits were I to enter into details respecting the chemical and physical reasons which led me to these definite conclusions. To settle one single point more than 2000 fractionations have been performed.

The meaning of the strongly marked symbolic lines had first to be ascertained. For a long time I had to be content with roughly translating one group of coloured symbols as "yttrium" and another group as "samarium," disregarding the fainter lines, shadows, and wings frequently common to both. Constant practice in the decipherment has now given me fuller insight into what I may call the grammar of these hieroglyphic inscriptions. Every line and shadow of a line, each faint wing attached to a strong band, and every variation in intensity of the shadows and wings among themselves, now has a definite meaning which can be translated into the common symbolism of chemistry.

In a mineral containing the rarer earths, those most widely separated in chemical properties are most easily obtained in a state of comparative purity by simple chemical means. For instance, in separating didymium from lanthanum, or samarium from yttrium, a few simple chemical reactions and a little waste will give these bodies in a state of purity; but when it comes to splitting up yttrium into its components ordinary chemical separation is useless, and fractionation must be pushed to the utmost limit, many thousand operations and enormous waste of material being necessary to effect even a partial separation.

Returning therefore, after this explanatory digression, to the idea of heavy and light atoms, we see how well this hypothesis accords with the new facts here brought to light. From every chemical point of view the stable molecular group, yttrium, behaves as an element. Excessive and systematic fractionation has acted the part of a chemical "sorting Demon," distributing the atoms of yttrium into several groups, with certainly different phosphorescent spectra, and presumably different atomic weights, though all these groups behave alike from the usual chemical point of view. Here, then, is one of the elements the spectrum of which does not emanate equally from all its atoms, but some atoms furnish some, other atoms others, of the lines and bands of the compound spectrum of the element. And as this is the case with one element, it is probably so in a greater or less degree with all. Hence the atoms of this element differ probably in weight, certainly in the internal motions they undergo.

Another important inference which may be drawn from the facts is, that the atoms of which yttrium consists, though differing, do not differ continuously, but *per saltum*. We have evidence of this in the fact that the spectroscopic bands characteristic of each group are distinct from those of the other groups, and do not pass gradually into them. We must accordingly expect, in the present state of science, that this is probably the case with the other elements. And the atoms of a chemical element being known to differ in one respect may differ in other respects, and presumably do somewhat differ in mass.

Restricted by limited time and means, even a partial separation of these atomic groupings is possible to me only with enormous difficulty. Have we any evidence that Nature has effected such a separation? The following facts, I think, supply this evidence.

The earth yttria occurs in several minerals, all extremely rare. These minerals are of very diverse chemical composition, and occur in localities widely separated geographically. Does the pure yttria (*pure* in respect to every other known element) from these different sources behave differently to the radiant-matter test? To the chemist hitherto the earth yttria has been the same thing, and has possessed the same properties whatever its source; but armed with this new power of seeing into the atomic groupings which go to make up yttrium, we find evidence of differentiation between one yttrium and another.

Thus when the samarskite yttrium was formed, all the constituent atoms—deep red, red, orange, citron, greenish blue, and blue[1]—condensed together in fair proportion, the deep red being faintest. In gadolinite yttrium the citron and greenish blue constituents are plentiful, the red is very deficient, the orange is absent, and the others occur in moderate quantities. In the yttrium from xenotime the citron is most plentiful, the greenish blue occurs in smaller proportion, the red is all but absent, and the orange is quite absent. Yttrium from monazite contains the greenish blue and citron, with a fair proportion of the other constituents; the greenish blue is plentiful, and the red is good. Yttrium from fluocerite is very similar to that from monazite, but the blue is weaker. Yttrium from hielmite is very rich in citron, has a fair quantity of blue and greenish blue, less of red, no orange, and only a very faint trace of deep red. Yttria from euxenite is almost identical with that from hielmite.

This is unlikely to be an isolated case. The principle is very probably of general application to all the elements. In some, possibly in all elements, the whole spectrum does not emanate from all its atoms, but different spectral rays may come from different atoms, and in the spectrum as we see it all these partial spectra are present together. This being interpreted means that there are definite differences in the internal motions which go on in the several groups of which the atoms of a chemical element consist. For example, we must now be prepared for some such events as that the seven series of bands in the absorption-spectrum of iodine may prove not all to emanate from every molecule, but that some of these molecules emit some of these series, others others, and in the jumble of all these kinds of molecules, to which is given the name "iodine vapour," the whole seven series are contributors.

To me it appears the theory I have here ventured to formulate, taken in conjunction with the diagram in Fig. 1, may aid the scientific imagination to proceed a step or two further in the order of elemental evolution. In the undulating curve may be seen the action of two forces, one acting in the direction of the vertical line, and the other pulsating backwards and forwards like a pendulum. Assume the vertical line to represent temperature slowly sinking through an unknown number of degrees, from the dissociation point of the first-formed element down to the dissociation point of those last shown on the scale. But what form of energy is represented by the oscillating line? Swinging to and fro like a mighty pendulum to points equidistant from a neutral centre; the divergence from neutrality conferring atomicity of one, two, three, and four degrees as the distance from the centre is one, two, three, or four divisions; and the approach to, or retreat from, the neutral line deciding the electro-negative or electro-positive character of the element—all on the retreating half of the swing being positive and all on the approaching half negative—this oscillating force must be intimately connected with the imponderable matter, essence, or source of energy we call electricity.

Let us examine this a little more closely. Let us start at the moment when the first element came into existence. Before this time matter, as we know it, was not. It is equally impossible to conceive of matter without energy, as of energy without matter; from one point of view the two are convertible terms. Before the birth of atoms all those forms of energy which become evident when matter acts upon matter, could not have existed—they were locked up in the *protyle* as latent potentialities

[1] For brevity I call them by their dominant spectrum band.

only. Coincident with the creation of atoms all those attributes and properties which form the means of discriminating one chemical element from another start into existence fully endowed with energy.

The pendulum begins its swing from the electro-positive side; lithium, next to hydrogen in simplicity of atomic weight, is now formed; then glucinum, boron, and carbon. Definite quantities of electricity are bestowed on each element at the moment of birth, on these quantities its atomicity depends,[1] and the types of monatomic, diatomic, triatomic, and tetratomic elements are fixed. The electro-negative part of the swing now commences; nitrogen appears, and notice how curiously position governs the mean dominant atomicity. Nitrogen occupies the position below boron, a triatomic element, therefore nitrogen is triatomic. But nitrogen also follows carbon, a tetratomic body, and occupies the fifth position counting from the place of origin; how beautifully these opposing tendencies are harmonised by the endowment of nitrogen with at least a double atomicity, and making its atom capable of acting as tri- and pentatomic. With oxygen (di- and hexatomic) and fluorine (mon- and heptatomic) the same law holds, and one half-oscillation of the pendulum is completed. Again passing the neutral line the electro-positive elements, sodium (monatomic), magnesium (diatomic), aluminium (triatomic), and silicon (tetratomic) are successively formed, and the first complete oscillation of the pendulum is finished by the birth of the electro-negative elements phosphorus, sulphur, and chlorine; these three—like the corresponding elements formed on the opposite homeward swing—having each at least a double atomicity depending on position.

Let us pause at the end of the first complete vibration and examine the result. We have already formed the elements of water, ammonia, carbonic acid, the atmosphere, plant and animal life, phosphorus for the brain, salt for the sea, clay for the solid earth, two alkalies, an alkaline earth, an earth, together with their carbonates, borates, nitrates, fluorides, chlorides, sulphates, phosphates, and silicates, sufficient for a world and inhabitants not so very different from what we enjoy at the present day. True the human inhabitants would have to live in a state of more than Arcadian simplicity, and the absence of calcic phosphate would be awkward as far as bone is concerned. But what a happy world it would be! No silver or gold coinage, no iron for machinery, no platinum for chemists, no copper wire for telegraphy, no zinc for batteries, no mercury for pumps, and, alas! no rare earths to be separated.

The pendulum does not, however, stop at the end of the first complete vibration; it crosses the neutral point, and now the forces at work are in the same position as they were at the beginning. Had everything been as it was at first the next element again would have been lithium, and the original cycle would have recurred, repeating for ever the same elements. But the conditions are not quite the same; the form of energy represented by the vertical line has declined a little—the temperature has sunk—and not lithium, but the one next allied to it in the series comes into existence—potassium, which may be regarded as the lineal descendant of lithium, with the same hereditary tendencies, but with less molecular mobility and higher atomic weight.

Pass we rapidly along the to-and-fro curve, and in nearly every case the same law is seen to hold good. The last element of the first complete vibration is chlorine. In the corresponding place in the second vibration we do not have an exact repetition of chlorine, but the very similar body bromine; and when for a third time the position recurs we see iodine. I need not multiply examples.

In this far-reaching evolutionary scheme it could not come to pass that the potential elements would all be equal to one another. Some would be unable to resist the slightest disturbance of the unstable equilibrium in which they took their rise; others would endure longer, but would ultimately break down as temperature and pressure varied. Many degrees of stability would be here represented; not all the chemical elements are equally stable, and if we look with scrutinising eyes we shall still see our old friend the missing link, coarse enough to be detected by ordinary chemical processes, associated in the groups containing such elements as iron, nickel, and cobalt; palladium, ruthenium, and rhodium; iridium, osmium, and platinum. Whilst in their more subtile form these missing links present themselves as representatives of the differences which I have detected and described between the atoms of the same chemical element.

Dr. Carnelley has pointed out that "those elements belonging to the even series of Mendeléeff's classification are always paramagnetic, whereas the elements belonging to the odd series are always diamagnetic." On this curve the even series to the left, as far as can be ascertained, are paramagnetic, and, with a few exceptions, all to the right are diamagnetic. The very powerful magnetic metals, iron, nickel, cobalt, and manganese, occur close together on the proper side. The interperiodic groups, of which palladium and platinum are examples, are said to be feebly magnetic, and, if so, they form the exceptions. Oxygen, which weight for weight is more magnetic than iron, comes near the beginning of the curve, while the powerfully diamagnetic metals, bismuth and thallium, are at the opposite end of the curve.

On the odd, or diamagnetic, half of the swing the energy appears to have considerable regularity, whilst it is very irregular on the opposite side of the curve. Thus, between the extreme odd elements, silicon (28), germanium (73), tin (118), the missing element (163), and lead (208), there is a difference of exactly 45 units, conferring remarkable symmetry on one half of the curve. The differences on the even side are 36, 42, 51, 39, and 53 (giving the missing element between cerium and thorium an atomic weight of 180); these at first sight appear conformable to no law, but they become of great interest when it is seen that the mean difference of these figures is almost exactly the same as that on the other side of the curve—viz. 44·2.

This uniformity of difference—actual on the one side and average on the other—brings out the important inference that, whilst on the odd side there has been little or no variation in the vertical force, minor irregularities have been the rule on the even side. That is to say, the fall of temperature has been very uniform on the odd side—where every element formed during this half of the vibration is the representative of a strongly-marked group—sodium, magnesium, aluminium, silicium, phosphorus, sulphur, and chlorine; whilst on the even side of the swing the temperature has sunk with considerable fluctuations, which have prevented the formation here of any well-marked groups of elements, with the exception of those of which lithium and glucinum are the types.

If we can thus trace irregularities in the fall of temperature, can we also detect any variation in the force represented by the pendulous movement? I have assumed that this represents chemical energy. In the early-formed elements we have those in which chemical energy is at its maximum intensity, while, as we descend, affinities for oxygen are getting less and the chemism is becoming more and more sluggish. Part may be due to the lower temperature of generation not permitting such molecular mobility in the elements, but there can be little doubt that the chemism-forming energy, like the fires of the cosmical furnace, is itself dying out. I have endeavoured to represent this gradual fading out by a diminution of amplitude, the curve being traced from a photographic record of the diminution of the arc of vibration of a body swinging in a resisting medium.

When we look on a curve of this kind there is a tendency to ask, What is there above and below that portion which is seen? At the lower end of our curve what is there to be noted? We see a great hiatus between barium (137) and iridium (192·5), which it seems likely will be filled up by the so-called rare elements. Judging from my own researches, it is probable that many of these earthy elements will be found included in one or more interperiodic groups, whilst the higher members of the calcium, the potassium, the chlorine, and the sulphur groups, together with the elements between silver and gold, cadmium and mercury, indium and thallium, antimony and bismuth, are still waiting to be discovered. We now come to an oasis in the desert of blanks. Platinum, gold, mercury, thallium, lead, and bismuth, all familiar friends, form a close little group by themselves, and then after another desert space the list is closed with thorium (233) and uranium (240).

This oasis, and the blanks which precede and follow it, may

[1] "Nature presents us with a single definite quantity of electricity. . . . For each chemical bond which is ruptured within an electrolyte a certain quantity of electricity traverses the electrolyte, which is the same in all cases."—G. Johnstone Stoney, "On the Physical Units of Nature," British Association Meeting, 1874, Section A. *Phil. Mag.*, May 1881.

"The same definite quantity of either positive or negative electricity moves always with each univalent ion, or with every unit of affinity of a multivalent ion."—Helmholtz, Faraday Lecture, 1881.

"Every monad atom has associated with it a certain definite quantity of electricity; every dyad has twice this quantity associated with it; every triad three times as much, and so on."—O. Lodge, "On Electrolysis," "British Association Report," 1885.

be referred with much probability to the particular way in which our earth developed into a member of our solar system. If this be so it may be that on our earth only these blanks occur, and not generally throughout the universe.

What comes after uranium? I should consider that there is little prospect of the existence of an element much lower than this. Look at the vertical line of temperature slowly sinking from the upper to the lower part of the curve; the figures representing the scale of atomic weights may be also supposed to represent, inversely, the scale of a gigantic pyrometer dipping into the cauldron where suns and worlds are in process of formation. Our thermometer shows us that the heat has been sinking gradually, and, *pari passu*, the elements formed have increased in density and atomic weight. This cannot go on for an indefinite extent. Below the uranium point the temperature may be so reduced that some of the earlier formed elements which have the strongest affinities are able to enter into combination among themselves, and the result of the next fall in temperature will then be—instead of elements lower in the scale than uranium —the combination of oxygen with hydrogen, and the formation of those known compounds the dissociation of which is not beyond the powers of our terrestrial sources of heat.

Let us now turn to the upper portion of the scheme. With hydrogen of atomic weight = 1, there is little room for other elements, save perhaps for hypothetical helium. But what if we get "through the looking-glass," and cross the zero-line in search of new principles—what shall we find the other side of zero? Dr. Carnelley asks for an element of negative atomic weight; here is ample room and verge enough for a shadow series of such unsubstantialities. Helmholtz says that electricity is probably as atomic as matter:[1] is electricity one of the negative elements, and the luminiferous ether another? Matter, as we now know it, does not here exist; the forms of energy which are apparent in the motions of matter are as yet only latent possibilities. A substance of negative weight is not inconceivable.[2] But can we form a clear conception of a body which combines with other bodies in proportions expressible by negative quantities?

A genesis of the elements such as is here sketched out would not be confined to our little solar system, but would probably follow the same general sequence of events in every centre of energy now visible as a star.

Before the birth of atoms to gravitate towards one another, no pressure could be exercised; but at the outskirts of the fire-mist sphere, within which all is *protyle*—at the shell on which the tremendous forces involved in the birth of a chemical element exert full sway—the fierce heat would be accompanied by gravitation sufficient to keep the newly-born elements from flying off into space. As temperature increases expansion and molecular motion increase, molecules tend to fly asunder, and their chemical affinities become deadened; but the enormous pressure of the gravitation of the mass of atomic matter outside what I may for brevity call the birth-shell would counteract this action of heat.

Beyond this birth-shell would be a space in which no chemical action could take place, owing to the temperature there being above what is called the dissociation point for compounds. In this space the lion and the lamb would lie down together; phosphorus and oxygen would mix without union; hydrogen and chlorine would show no tendency to closer bonds; and even fluorine, that energetic gas which chemists have only isolated within the last month or two, would float about free and uncombined.

Outside this space of free atomic matter would be another shell, in which the formed chemical elements would have cooled down to the combination-point, and the sequence of events so graphically described by Mr. Mattieu Williams in "The Fuel of the Sun" would now take place, culminating in the solid earth and the commencement of geological time.

And now I must draw to a close, having exhausted not indeed my subject, but the time I may reasonably occupy. We have glanced at the difficulty of defining an element; we have noticed ton the revolt of many leading physicists and chemists against the ordinary acceptation of the term element. We have weighed the improbability of their eternal self-existence, or their origination by chance. As a remaining alternative we have suggested their origin by a process of evolution like that of the heavenly bodies according to Laplace, and the plants and animals of our globe according to Lamarck, Darwin, and Wallace. In the general array of the elements, as known to us, we have seen a striking approximation to that of the organic world. In lack of direct evidence of the decomposition of any element, we have sought and found indirect evidence. We have taken into consideration the light thrown on this subject by Prout's law, and by the researches of Mr. Lockyer in solar spectroscopy. We have reviewed the very important evidence drawn from the distribution and collocation of the elements in the crust of our earth. We have studied Dr. Carnelley's weighty argument in favour of the compound nature of the so-called elements from their analogy to the compound radicals. We have next glanced at the view of the genesis of the elements; and, lastly, we have reviewed a scheme of their origin suggested by Prof. Reynolds's method of illustrating the periodic classification.

Summing up all the above considerations we cannot, indeed, venture to assert positively that our so-called elements have been evolved from one primordial matter; but we may contend that the balance of evidence, I think, fairly weighs in favour of this speculation.

This, then, is the intricate question which I have striven to unfold before you, a question that I especially commend to the young generation of chemists, not only as the most interesting, but the most profoundly important, in the entire compass of our science.

I say deliberately and advisedly the *most interesting*. The doctrine of evolution, as you well know, has thrown a new light upon and given a new impetus to every department of biology, leading us, may we not hope, to anticipate a corresponding wakening light in the domain of chemistry?

I would ask investigators not necessarily either to accept or to reject the hypothesis of chemical evolution, but to treat it as a provisional hypothesis; to keep it in view in their researches, to inquire how far it lends itself to the interpretation of the phenomena observed, and to test experimentally every line of thought which points in this direction. Of the difficulties of this investigation none can be more fully aware than myself. I sincerely hope that this my imperfect attempt may lead some minds to enter upon the study of this fundamental chemical question, and to examine closely and in detail what I, as if amidst the clouds and mists of a far distance, have striven to point out.

[1] "If we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid concluding that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity."—HELMHOLTZ, Faraday Lecture, 1881.

[2] "I can easily conceive that there are plenty of bodies about us not subject to this intermutual action, and therefore not subject to the law of gravitation."—SIR GEORGE AIRY, "Faraday's Life and Letters," vol. ii. p. 54.

NOTES

A REUTER's telegram dated Grenada, August 29, states that during the solar eclipse of that morning good photometric observations were made by Prof. Thorpe. The light during the middle of totality was less than from the full moon. We learn from later telegrams dated Grenada, August 31, that the eclipse of the sun has been well observed by the British Astronomical Expedition, and that in the observations taken it was noticed that the corona extended nearly two diameters from the sun, and exhibited a feathery structure at the poles. Good photographs have been obtained of the coronal spectrum in the blue end. The spectrum was similar to that of the eclipse of 1883, observed on the Caroline Islands.

THE celebrations connected with the Chevreul centenary took place in Paris on Tuesday last. The first demonstration was that of the National Society of Agriculture, to which M. Chevreul was elected member forty-six years ago, and of which he is elected President every alternate year. A commemoration medal was struck by the same Society. At three o'clock M. Chevreul received the congratulations of the members of the Academy of Sciences. The principal ceremony of the day was the unveiling of the statue of M. Chevreul in the hall of the new Museum at the Jardin des Plantes. The walls of the room, which are of vast dimensions, were hung with red velvet, and

decorated with Gobelins tapestry and flowers. Spaces were reserved for Senators, Deputies, members of the Diplomatic Corps, and other distinguished persons. M. Goblet, Minister of Public Instruction, sat on M. Chevreul's right, and M. Floquet on his left. M. Frémy, the Director of the Museum, addressing M. Chevreul, said that the professors of the Museum, anticipating the future, had presented to him this statue. He then referred to the work of M. Chevreul in various branches of science, mainly in chemistry, and the results of his discoveries in industry. M. Zeller, President of the five Academies, M. Brock, representing the three Academies of Science of Scandinavian countries, M. Boscha, delegate of the Agricultural Society of Moscow, and the Italian Ambassador, also offered their congratulations to the venerable *savant*. The last speaker was the Minister of Public Instruction, who spoke, on behalf of the State, of the many ties which connected the great professor and chemist with the Ministry of Public Instruction. "The century which precedes our time," said M. Goblet, "belonged above all to science. What gave it its true character was the recent rise of scientific research, pursuing in the study of Nature the means of extending the domain of human power. Amongst the various branches of science, that to which M. Chevreul devoted himself—chemistry—is certainly one of the most fruitful, and one of those which owes most to French genius. Thanks to great French chemists and to M. Chevreul, France marches in the foremost rank of the nations which modern science guides." A banquet was given in the evening at the Hôtel de Ville. Several Ministers of State were present. The toast of M. Chevreul's health was proposed by M. Floquet, and supported by the Minister of Public Instruction. The festival which followed was very brilliant, ending with a torchlight procession, in which two squadrons of cuirassiers and a considerable body of infantry with several bands took part. Various Societies, all the members carrying Chinese lanterns, also joined the procession, which marched from the Hôtel de Ville through the principal streets and boulevards to the Place de la République. The streets through which the procession passed were thronged with dense masses of spectators.

On the 28th ult. His Excellency Tcheou Meou-Ki, Director of the Chinese Mission of Public Instruction, paid a visit, with the mandarins attached to his person, to M. Chevreul at his house. He handed to the illustrious chemist a Chinese document expressing in old characters every wish for his happiness and long life. It appears that there is living at this moment in China a Chinese *savant* who at the age of 100 years has just passed his examinations and been admitted a member of the highest academy of the mandarins. The interpreter explained to M. Chevreul that his Chinese visitors considered the fact that two *savants* a hundred years of age were living, one in France and the other in China, was a link connecting the learning of the two countries. When the Chinese Mission had retired, M. Chevreul received a deputation of the inhabitants of the Rue Chevreul, who presented him with a bouquet.

The last number of *La Nature* contains a biographical sketch, with several portraits, of M. Chevreul, from which it appears that he was born at Angers on August 31, 1786, his father being a physician and surgeon. It is noticeable that the father reached the age of ninety-one, and the mother died aged ninety-three. M. Chevreul as a lad witnessed some of the scenes of the conflict in La Vendée, and he saw the guillotine at work in Angers. The old University of the town having been swept away by the Revolution, he received his early education at the Central School of the place. He left this at the age of seventeen, and turned towards Paris, which was at that time peculiarly fortunate in possessing as teachers and professors eminent men in every branch of science. Fourcroy, the Professor of Chemistry at the College of France, was engaged in improving higher education, and left the work of his Chair largely to his demonstrator, Vauquelin, of whom Dumas said that he was wholly a chemist, a chemist every day of his life, and during the whole of each day. Chevreul entered under this teacher, and soon distinguished himself so much that he was allowed to take charge of the laboratory when twenty years of age. At the same time he taught at the Collège Charlemagne; four years later he was appointed Demonstrator to the Museum, and at thirty was appointed special Professor of Chemistry in charge of the dyeing department at the Gobelins. One of his earliest discoveries was that of margarine, oleine, and stearine in oils and fats. The last of these furnishes stearic acid, and thus an important industry like that in stearic candles was founded. His studies in fatty bodies, and his theory of saponification (1823) have not only created new industries, but they opened immense horizons in organic chemistry. Between 1828 and 1864 he studied colours, and from time to time published memoirs on the progress of his work. In 1826 he took his seat in the Academy of Sciences, and in 1830 he was appointed Director of the Museum of Natural History. His life now is spent between this institution, the Gobelins, and the Institute of France. He never fails to attend the Monday meetings of the Academy of Sciences. The number of his papers, memoirs, &c., is very great. Amongst them is one written in 1832, on the divining-rod, and another in 1853, in which he dissipated the mystery surrounding table-turning and similar manifestations. M. Chevreul remained in Paris during the siege of 1870-71, working steadily in his laboratory. It was soon after this that an expression in a letter he wrote to a friend led to the honourable title of "Doyen des étudiants de France" being affixed to his name. Although he possesses a large fortune, he still carries on his work at the institutions with which he is connected, and prosecutes his experiments with a juvenile lightness of touch. He is exceedingly temperate, drinking nothing but water or beer, but his longevity is not due to this; he owes it to a robust constitution and to a life wisely ordered, regular, and laborious. "It is," concludes M. Tissandier, "a great and beautiful sight presented by this centenarian, who, like an old oak, shelters under his shadow successive generations. Deaf to the sounds of this world, he has chosen to work alone in his laboratory, where his ever-wakeful intelligence is unceasingly attracted to the rays of eternal truth."

In reply to a question from Sir John Lubbock, Mr. Ritchie, the President of the Local Government Board, stated last week that considerable progress had been made by the Committee appointed last session to inquire and report on the subject of M. Pasteur's researches with reference to the prevention of hydrophobia. A sub-Committee visited Paris and had several long interviews with M. Pasteur, who explained to the members most fully and unreservedly the whole details of his treatment. The Committee examined a large number of the persons who had undergone treatment, and so far as this investigation is concerned, the Committee were fully satisfied that M. Pasteur's treatment had been effective. They hope before long to be in a position to report the results of their investigation to the Local Government Board, but before doing so they are anxious that time should be allowed for the Committee to ascertain that experiments on animals conducted on behalf of the Committee have yielded the same results as those detailed and demonstrated to them by M. Pasteur.

We regret to announce the death of Dr. James G. Wakley, editor of the *Lancet*, at his residence, Heathlands Park, Longcross, near Chertsey, on August 30. He was the youngest son of the late Thomas Wakley, founder of the *Lancet*, Member of

Parliament for Finsbury, and coroner for Middlesex. He became a member of the Royal College of Surgeons of England in 1849, and graduated Doctor of Medicine at King's College, Aberdeen, in 1852. At his father's death in 1862 he became editor of the *Lancet*, the duties of which position he discharged for nearly twenty-five years, continuing, in spite of much recent suffering, active in his work up to last Easter.

THE death is announced from Paris of M. Laguerre, Professor of Mathematical Physics in the College of France, and a distinguished mathematician, at the age of fifty-two. In his earlier years he was an officer in the artillery. He wrote and published in the *Proceedings* of various learned Societies numerous mathematical papers, but he never published a volume.

THE annual Pharmaceutical Congress commenced its sittings at the Mason College, Birmingham, on the 31st ult., under the presidency of Mr. Greenish, of London.

ON Friday, August 27, about midnight, an earthquake was felt all over the Levant, and as far to the west as Malta. At Alexandria the shock was felt fifteen minutes after midnight; its apparent direction was from west to east; at Athens a severe shock was felt about the same time. Its force was greatest and most destructive in Greece and the Ionian Islands. In the South-Western Peloponnesus, and particularly in the department of Messenia, towns and villages were destroyed. The towns of Filiatra and Gargaliano and Marathoupolis were laid in ruins, and Kyparassi and Choremi in Arcadia are similarly destroyed. The Eparch has, in consequence of the destruction of the houses, had to telegraph for tents for the people. Over 120 persons were killed, and a large number injured. The Greek Government has despatched four war-vessels with necessaries to relieve the inabitants. From Zante comes news that all the houses in Pyrgos have been destroyed. The shock was felt also in Zante, not a house having escaped damage, although no loss of life has occurred. Strong shocks were felt all over Greece. Some indications of the nature of the weather prior and subsequent to the shock are given by Reuter's Correspondent at Zante. For some time past extraordinary atmospherical disturbances, excessive heat, dead calms, and unusually high tides occurred. At 25 minutes past 11 on Friday night, after a day of heavy and threatening weather, the whole of Zante was racked with a most violent, but steady and undulating, earthquake lasting 15 seconds. The centre of the earthquake, the same correspondent says, was in the sea, 30 miles south-east of Zante, where it smashed the telegraph cable. After the shock the weather was threatening, indicating an approaching storm, and soon after a fearful storm burst over Corfu. Patras and the whole of the Ionian Islands suffered from the earthquake. The position of the centre of this shock is said to indicate some violent volcanic submarine agitation to the south of Zante. The weather after the earthquake remained menacingly heavy, and it was expected that other shocks would follow. At 11 o'clock the same night a shock was felt at Naples. At Brindisi an upheaval movement of the earth, lasting two minutes, was felt, followed by an undulatory movement of about the same duration. There were also two successive prolonged shocks at Foggia, and two undulatory movements at Caserta. At Taranto there were two very sharp shocks, one vertical, the other undulatory, causing great alarm to the inhabitants, who passed the night in the fields for safety. There was however no loss of life nor any serious damage at the places visited by the seismic disturbance. The Governor of Malta also telegraphs to the Colonial Office that a severe earthquake visited the island at 11 o'clock the previous night, causing much alarm, but no serious injury to buildings. No lives were lost. It appears that the correspondent in Alexandria who states that the earthquake appeared to travel from west to east is correct. The wave was first felt at Malta about 11, a little later in Naples (very slight), and in various parts of Calabria, then about midnight in the Ionian Islands, then in Greece, and at fifteen minutes past midnight in Alexandria.

THE Premier of New South Wales has laid before Parliament the proposals of his Government for the celebration of the centenary of that colony in 1888. Amongst others, the New South Wales Government propose inviting the members of the British Association to hold their annual meeting for that year in Sydney, and the Premier stated that he had already communicated with the Association on the importance of the visit. Great stress was laid on the fact that the invitations would be extended to all British Universities, literary, scientific, and art Societies.

WE have received parts 1 and 2 of vol. ix. of the *Transactions* of the Seismological Society of Japan. Prof. Knott discusses the well-worn subject of earthquake frequency, but in a wholly new and original way. His object is to determine the effect of the various causes which are said to influence earthquakes, and his conclusion is that the annual periodicity in earthquake frequency, when it does exist, finds a possible explanation in the annual periodicity of two well-known meteorological phenomena—namely, snow accumulations over continental areas and barometric gradients. No other cause, he says, that can be imagined or named fulfils all the conditions. Mr. Shida describes an automatic current recorder of his own invention. The resolution of the International Electric Congress held in Paris in 1884, that observations of earth-currents should be pursued in all countries was communicated to various Governments, to that of Japan amongst the number. Mr. Shida is Chief Engineer to the Japanese Telegraph Department, and it devolved on him to take the subject up. To this fact, doubtless, we also owe the third paper, which is by the same gentleman, on earth-currents. He describes briefly the work that has been done in the subject in the past, what is being done, and what might be done in Japan. From an examination of the magnetic observations made at the Meteorological Department of Tokio it appears that the declination variations are not the effect of earth-currents, for, if this were so, then an increase of the western declination ought to correspond to a decrease of earth-current flowing from north to south, not an increase, as has been found by actual observation. The results show that both magnetic and earth-current variations are regulated by the same cause or causes, and that the sun plays an important part in producing the effects which are observed. The fact, however, that there appear to be two maxima and two minima in these variations tends to show that they are in part due to the action of the moon. The study of earth-currents, says Mr. Shida, has not advanced *pari passu* with other branches of seismological science, and he desires to establish a system of observation of the currents, and to devise and improve methods of observing. The second part of the *Transactions* contains an elaborate and exhaustive paper (it fills nearly 200 printed octavo pages), by Prof. Milne, on the volcanoes of Japan. It represents the labour and collections of about ten years, and is deserving of special detailed notice. We are glad to observe, from a notice sent with the numbers, that the Japanese *Transactions* of the Society (*i.e.* those written or translated into Japanese) have now reached their third volume. Taken all in all, this Society is by far the most active and thriving of all the learned Societies of the Far East, and we have little doubt that it owes a great part of its vitality to the fact that Japanese men of science are pursuing the work inaugurated by Prof. Milne with the enterprise and ardour of their race.

PRINCE PUTIATIN has presented to the Russian Archæological Society a stone slab which was recently found in the course of some excavations at the Bologne station on the St. Petersburg and Moscow Railway, along with some stone weapons and

utensils. A representation of the constellation of the Great Bear was, although rudely, carefully drawn on the slab. It may be remembered that some years ago a similar slab was found near Weimar.

THE additions to the Zoological Society's Gardens during the past week include a White-fronted Capuchin (*Cebus albifrons*) from Central America, presented by Mr. H. A. Blake; a Mississippi Alligator (*Alligator mississippiensis*) from Florida, presented by Miss Janet D. White; a Common Gannet (*Sula bassana*), British, presented by Mr. F. E. Hatfield; two Dominican Kestrels (*Tinnunculus dominicensis*), two Green Bitterns (*Bictorides virescens*), from West India, presented by Dr. A. Boon, F.R.C.S.; a Raven (*Corvus corax*), British, presented by Mr. Robert Galland; a Ring-tailed Coati (*Nasua rufa*), a Globose Curassow (*Crax globicera*), from Central America, a Clouded Iguana (*Cyclura carinata*), from Cuba, deposited; a Black-necked Swan (*Cygnus nigricollis* ♀) from Chili, purchased; a Leopard (*Felis pardus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

NOTES ON VARIABLE STARS.—Mr. T. E. Espin, Observer to the Liverpool Astronomical Society, announces in the Society's *Circular*, No. 6, that the star D.M. + 8°·3780, stated in *Circular* No. 2 (NATURE, vol. xxxiv. p. 110) to be probably variable, passed its maximum about June 4, at which time its magnitude was 6·8. Since this date it has diminished in brightness, and on August 20 it was only 8·2. The star would seem to be a long-period variable. Its place for 1885 is R.A. 18h. 32m. 51s., Decl. + 8° 43′·5. Mr. Espin also states that he has detected variation in the red star D.M. + 47°·3031, which passed a minimum about the end of April. On May 14 it was only 8·9, since which it has increased, and is now 7·7. This star also is a long-period variable. Its place for 1885 is R.A. 20h. 5m. 58s., Decl. + 47° 28′·9. It precedes 32 Cygni by 5m. 57s., and is 9′ north of it.

Circular No. 7 states that—(1) The observations of 10 Sagittæ on sixty nights since 1885 November 28 give: Period = 8·32134d., Epoch of Max. 1886 July 17·56d. A minimum occurs on 1886 September 1·6d., and a maximum on 1886 September 5·5d. (2) The star D.M. + 17°·3940 was observed as 9·5 on April 26 last. From this date it increased, and on June 13 it was 8·3. Latterly it has diminished, and on August 20 it was 8·7. Vogel gives the spectrum as III*b*. ! Dunér as III*a*. !! The star's place for 1885 is R.A. 19h. 16m. 33s., Decl. + 17° 26′·4.

WINNECKE'S COMET.—From the *Dun Echt Circular*, No. 124, we learn that this periodical comet has been found at Cape Town. It is described as circular, less than 1′ in diameter, as bright as a star of the 10th magnitude, and as having some central condensation but no tail. Its observed place was Greenwich M.T. Aug. 20, 5h. 47m. 54s., R.A. 13h. 10m. 21·5s., Decl. 1° 8′ 17″ S. The daily motion, according to Lamp's ephemerides (*Astronomische Nachrichten*, No 2731) is about *plus* 3·3m. and 32′ *south*.

THE OBSERVATORY OF YALE COLLEGE.—The report of the work done at this Observatory during the year ending June 1, 1886, has recently been issued. The chief astronomical work is that done with the heliometer in charge of Dr. W. L. Elkin. With this instrument considerable progress has been made with the triangulation of the Pleiades, completing the series obtained in the previous year. All the stars have now been observed on from ten to twelve nights, and a total of over 1600 measures of distance and 700 of position-angle are available for discussion. The principal observing work accomplished by Dr. Elkin, has, however, been in connection with the scheme for determining the average parallax of the first-magnitude stars as a step towards the more comprehensive plan proposed by Gill and Elkin in concert. It is proposed at present to take the ten brightest stars in the northern hemisphere and observe them each from sixteen to twenty times at epochs of maximum parallactic displacement, using a favourably situated pair of comparison stars—in some cases a double pair, or four stars. Arcturus, with its large proper motion, presents an object of especial interest, and it has been taken up in a more exhaustive manner with six pairs of comparison stars, five of which have been successfully followed up so far. The whole work is progressing satisfactorily, over 200 sets of measures having been made, and is rather more than half completed, the working plan extending until February 1887. Astronomers will await with interest the completion and publication of Dr. Elkin's important researches.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 SEPTEMBER 5-11

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 5

Sun rises, 5h. 21m.; souths, 11h. 58m. 34·8s.; sets, 18h. 36m.; decl. on meridian, 6° 45′ N.: Sidereal Time at Sunset, 17h. 35m.

Moon (at First Quarter) rises, 13h. 38m.; souths, 18h. 11m.; sets, 22h. 41m.; decl. on meridian, 17° 44′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury ...	3 38 ...	10 53 ...	18 8 ...	13 44 N.

Meteor Showers

Meteors have been observed at this season from the following radiants:—Near *o* Eridani, R.A. 55°, Decl. 6° S.; from Camelopardus, R.A. 60°, Decl. 60° N.; from near μ Persei, R.A. 65°, Decl. 46° N.; from near μ Tauri, R.A. 65°, Decl. 6° N.; and near α Pegasi, R.A. 345°, Decl. 13° N.

SCIENTIFIC SERIALS

Journal de Physique, July.—Prof. Mascart, on magnetisation. A study of the secondary effect produced by the reaction of the polar surfaces on the magnetising field. The author calculates also the influence of the earth's magnetism in producing temporary alteration in the magnetisation of a needle during oscillation, an effect which he finds to have been often exaggerated, and not to exceed 1/1000 part of the whole magnetisation.—P. Duhem, on the calorific capacity of dissociable gaseous combinations. Discussion and expansion of the formulæ

of Willard Gibbs to explain the variations of specific heat of such bodies as nitric oxide and acetic acid. The results confirm the idea that such variations are due to the gradual dissociation of polymeric forms.—G. Lippmann, an absolute spherical electrometer. Two hollow metal hemispheres, one fixed, the other held by a trifilar suspension, when similarly electrified, repel one another, with a force actually proportional to the square of the potential. The displacements are read optically.—MM. Bichat and Blondlot, on an absolute electrometer with continuous indication. This is an apparatus of three concentric cylinders, the innermost of which is suspended from a balance. The theory of it is already known.—P. Janet, on the formula of Van der Waals, and its application to capillary phenomena.—F. and W. Kohlrausch, the electro-chemical equivalent of silver (abstracted from *Wiedemann's Annalen*).

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, August 23.—M. Fizeau in the chair.—Elliptical elements of Brooks's Comet III. 1886, by Mr. J. R. Hind. The elliptical orbit, deduced from the observations made at Nice on May 25 and July 1, and at Algiers on June 3, is as under:—

T = 1886 June 6·57145 Greenwich Mean Time

$$\left.\begin{array}{lr} \pi \;\ldots\;\ldots & 229^\circ\ 45'\ 58''\!\cdot\!0 \\ \Omega \;\ldots\;\ldots & 53\ \ 3\ 25\cdot7 \\ \iota \;\ldots\;\ldots & 12\ \ 56\ \ 1\cdot8 \end{array}\right\}\text{Mean Equinox 1886·0}$$

$$\begin{array}{ll} \phi \;\ldots\;\ldots & 37\ \ 27\ \ 10\cdot2 \\ \log a \;\ldots & 0\cdot5329478 \\ \mu \;\ldots\;\ldots & 563''\cdot0992 \\ \text{Period} \;\ldots & 6^{a}\cdot301 \end{array}$$

—On the measurement of very strong pressures and on the compressibility of fluids, by M. E. H. Amagat. For the measurement of very high pressures the author has adopted the principle of the manometer with differential pistons. In order to obtain accurate results, the condition had to be realised of maintaining the pistons in complete action while keeping them perfectly air-tight. The reading of the volumes of compressed fluid was effected by the process already indicated by Prof. Tait, of Edinburgh. Water and ether have been studied at zero and at the two respective temperatures of 20° and 40° C. Respecting the variation with pressure, it is shown that the coefficient diminishes gradually with the increase of pressure, and this takes place throughout the whole scale of pressures, contrary to the opinion of some physicists. At 3000 atmospheres the volume of water was reduced one-tenth, and its coefficient of compressibility one-half. This coefficient between 2590 and 2981 atm. was 0·0000238, and that of ether between 1623 and 2002 atm. 0·000045. The study of ether will be continued and pushed to 3000 atm., and in a future communication will be given the coefficients of compressibility and of dilatation for several other fluids up to 3000 atm. A number of gases will then be examined with the same apparatus and within the same limits of pressure.—On the purple of the solar spectrum, by M. Camille Koechlin. The solar spectrum yields only two simple colours, blue and yellow. The third is blended with yellow and blue to constitute the reds on the one hand, the violet, on the other, purple being red deprived of yellow or violet deprived of blue, or simply the spectrum without yellow or blue. If on the red of one be projected the blue of another spectrums or on the violet of the first the yellow of the second, the result is purple. The red or the violet may again be restored by applying to the purple the yellow or blue of a third spectrum. And if these applications be made with reversed prisms, so that the complementary colours reciprocally cover each other, the spectrum will present at both extremities a purple region with yellowish-white interval. Purple, being a simple colour, will thus never be obtained by mixture, but only by extracting the yellow from a red or the blue from a violet. The solar spectrum contains the elements of all shades, either by mixtures or by diluting with white or extinction with black. In the latter case the colours containing blue preserve their tint, while those on the opposite side of the yellow become changed in character. Thus green, blue, and violet yield the so-called deep greens, blues, and violets, while the yellow, orange, red, and purple cannot be intensified, but pass over to olive, brown, garnet, or amaranth.—On the branchial apparatus and muscular and nervous systems of *Amaræcium torquatum*, by M. Charles Maurice. In this Compound Ascidian, which abounds at Villefranche-sur-Mer, the branchial apparatus presents thirteen rows of stigmata, and is otherwise characterised by three fundamental peculiarities connected with the transverse sinus.—On a larva of *Lampyris noctiluca* surviving the loss of its head, by M. François. This specimen, which had lost the whole of the cephalic region, was found in a perfectly healthy and normal condition, and although destitute of any buccal orifice, it showed on dissection an abundance of adipose tissue. The œsophagus, however, had changed its position, and contained no trace of alimentary matter.—On the cyclone that swept over the Gulf of Aden in June 1885, by Admiral Cloué. As supplementary to the previous statement on this subject, the writer has collected further details from the captains of some English and Dutch vessels overtaken by the storm, and from Obock regarding the caravan which was *en route* for Shoa when the whirlpool swept by.—Remarks on Dr. W. C. Gore's memoir on the "Projectiles of the Future," presented to the Academy, by M. Larrey. In the interests of humanity, which are above those of war, it is argued that the use of explosives should be more and more restricted, and replaced by projectiles calculated rather to wound than to kill the combatants. With this object it is proposed to substitute for the explosive bullets now in use the so-called "Lorenz" projectiles, which are described as "the missiles of the future."

THE ECLIPSE EXPEDITION

NOTHING could have exceeded the magnificent manner in which the authorities of Grenada, and chiefly His Excellency Governor Sendall, and the commanders of the ships detailed to assist the Expedition—Her Majesty's ships *Fantôme*, *Bullfrog*, and *Sparrowhawk*—have met the wishes of, and lent assistance to, the Expedition.

As a consequence, at this time of writing (August 20) all the observers, with the exception of the Chief of the Expedition, are at their posts, with huts and instruments erected, and as much skilled assistance as they can possibly desire. The stations actually occupied so far are as follows:—

(1) Carriacou. Rev. S. J. Perry and Mr. Maunder. This party has the *Bullfrog*, two officers of which will assist, as well as Lieut. Helby of the *Sparrowhawk*.

(2) Boulogne. Prof. Tacchini and Mr. Turner. Lieut. Smith, of the *Sparrowhawk*, and a petty officer and skilled artificer, assist this party.

(3) Hog Island. Prof. Thorpe. The *Fantôme* is anchored near the observing-station, and Prof. Thorpe will have the assistance of the officers.

(4) Prickly Point. Capt. Darwin and Dr. Schuster. One or two officers of the *Fantôme*, and Capt. Maling, the Colonial Secretary, assist this party.

The fifth station, to be eventually occupied by Mr. Lockyer, is at Green Island, at the north-east corner of Grenada. Capt. Oldham, of the *Sparrowhawk*, Mr. Beresford (the Clerk of the Council), the Chief of the Police, Mr. Wright, and Dr. Boyd will assist him.

The parties at Boulogne, Prickly Point, and Green Island occupy houses which have been placed at the disposal of the Expedition by Col. Duncan, Mr. Chadwick (the Treasurer of the Island), and Mr. Belton respectively; nothing can exceed the kindness which the Expedition has received, and the assistance rendered has been so effectual, that so far everything has gone without a hitch. The labours of the Governor in the cause of the Expedition have been unceasing; he planned a hut and sent a model to Barbados, and when it was approved (by telegraph) he had four ready awaiting the arrival of the parties, which were thus enabled to proceed at once to their stations.

The weather chances are doubtful, but certainly they have improved since the arrival of the Expedition. The observations of the local cloud conditions have been so continuous lately, not only by the observers themselves, but by many at the request of the Governor before the arrival of the Expedition, that there is no question that the best stations are occupied, and it is a matter of general satisfaction that Carriacou has been added to the line of stations. The local idea is that the hurricane which passed over St. Vincent—and so nearly over Grenada!—last Monday has cleared the air, as it has been noticed that spells of fine weather generally follow them.

The *Fantôme* comes in on Sunday to convey the Green Island party to their station; although this will leave very little time for the party to establish itself, it has been considered desirable to leave the southern observers undisturbed as long as possible. The Governor and Mr. Lockyer will proceed in her to Carriacou to inspect the station there, while the hut and instruments are being erected at Green Island. The last week has been spent here in erecting and dismounting the instruments and overhauling everything, so that no time will be lost at the station itself.

There are photographic difficulties ahead: with the ordinary plates brought out here, the film simply disappears in the developer in consequence of the usual temperature of the water, about 80°. The Germans and Americans are now supplying plates here which stand this temperature easily, but they do not seem to be known in England. It looks very much as if it will be safer to take some if not all of the photographs obtained—if any *are* obtained—to be developed at home.

The Expedition will arrive in England on September 18.

St. George, Grenada

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873-76 *under the Command of Capt. G. S. Nares, R.N., F.R.S., and Capt. F. T. Thomson, R.N.* Prepared under the Superintendence of the late Sir C. Wyville Thomson, F.R.S., &c, and now of John Murray, one of the Naturalists of the Expedition. Zoology—Vol. XIV. By Prof. W. A. Herdman, and Hjalmar Théel. (Published by Order of Her Majesty's Government, 1886.)

VOLUME XIV. of the Zoological Series of these Reports contains Parts 38 and 39. Part 38 forms the second part of Prof. W. A. Herdman's Report on the Tunicata collected by the Expedition. It will be remembered that the first part was published in 1882, and that it treated of the Simple Ascidians. The Compound Ascidians are described in the present Report, and the free-swimming or pelagic forms will form a third and concluding Report. The Compound Ascidians have always been regarded by biologists as a most difficult group to describe. The impossibility of finding good diagnostic characters in external markings or general contour compels the investigator to search for such in minute internal structure—a laborious proceeding, and one that up to this had had no practical illustration. The large collection of Compound Ascidians made during the Expedition represented 102 species or well-marked varieties, and these are arranged in twenty-five genera. Eighty-eight of the species and ten of the genera are described here for the first time, and two new families have been established.

The families and genera seem to be uniformly distributed, but they are more numerously represented in the southern than in the northern hemisphere; indeed, the Compound Ascidians, like the Simple Ascidians, attain their greatest numerical development in the southern temperate zone. The Botryllidæ appear to be confined to the northern hemisphere, having there a very wide range. The Distomidæ are well represented in both hemispheres. The Polyclinidæ almost exclusively belong to the

southern hemisphere. The Diplosomidæ are from tropical seas. The family of the Cœlocormidæ is only known from the southern hemisphere. In the Didemnidæ the genera are well represented in both hemispheres, while in that of the Polystyelidæ the southern and northern forms belong to different genera.

The Compound Ascidians are not deep-sea forms. While between shore-mark and a depth of 50 fathoms over 60 species and varieties were found, but 12 species were met with at depths between 100 and 250 fathoms; 4 species extended to a depth of 500; 7 species to a depth of 1000 fathoms; and one strange form, *Pharyngodictyon mirabile*, was found at a depth of 1600 fathoms. While as a matter of course the shallow-water forms have been better known from being so much more easily collected than the deep-sea species, still Prof. Herdman seems amply justified in his conclusions that the Compound Ascidians are essentially "a shallow-water group, that they are abundant around coasts in a few fathoms of water, and that they rapidly decrease in numbers as greater and greater depths are reached."

As to the phylogeny of the group, the author has come to the conclusion that the Compound Ascidians are polyphyletic in origin, being made up of several branches, which at differing periods have arisen from the Simple forms.

As introductory to the description of new genera and species, we find a very complete and most instructive chapter devoted to the history, bibliography, and anatomy of the group. The general anatomical details are illustrated by some excellent woodcuts. The details of the anatomy of the various species are given in connection with their description, and are largely illustrated on the forty-nine plates drawn by Prof. Herdman which accompany the memoir. The investigation of the Ascidians, despite the existence of some few brilliant memoirs, is now for the first time done justice to; and, while we congratulate the author on his excellent work, we recognise in it not only an elaborate Report, but in addition a monograph of a, to this, very imperfectly known group.

Part 39 is a Report on the Holothuroideæ, by Hjalmar Théel, Part 2. In the second portion of this Report on these soft-bodied Echinoderms, Théel has not rested satisfied with giving a description only of the new forms of the groups Apoda and Pedata, which were brought home by the Expedition, but he has added a series of short accounts of all the forms known, even quoting the doubtful or little-known forms. Thus we have in this report also a veritable monograph of another most interesting group. Although unable to say much as to the bathymetrical distribution of these forms, still the *Challenger* dredgings have added many facts to our previous knowledge. Up to 1872 very few forms were known from depths exceeding 100 fathoms, and scarcely one from below 200 fathoms. Now we know of a number of forms met with at a depth of 500 fathoms, and these are generally distinct from shallow-water forms though belonging to the same genera. Several species have a vast bathymetrical distribution, some individuals still living near the shore, while others have descended without any notable change to depths of from 5 to 700 fathoms. Some few belong to genera that have no representatives in depths shallower than 500 fathoms. Among the very deep-sea forms we find *Cucumaria abyssorum*, at a depth of from 1500 to 2223 fathoms; *Synapta abyssorum*, at a depth of 2350 fathoms; *Pseudostichopus villosus*, at a depth of 1375 to 2200 fathoms; and the deepest-living of all the forms, *Holothuria thomsoni*, at a depth of from 1875 to 2900 fathoms. Some fifty-three new species or strongly-marked varieties are described and figured. A valuable bibliography is annexed Many imperfectly-described species have been re-described from fresh specimens, thus rendering this Report of immense value to the working zoologist.

OUR BOOK SHELF

Miscellaneous Papers relating to Indo-China. 2 Vols. Trübner's Oriental Series. (London: Trübner and Co., 1886.)

In Oriental matters, more than in any other branch of investigation, the student is beset at every step by the difficulty of knowing what has been done already, for, besides books and papers published in London and other European capitals (which are accessible enough), there are those published in the East itself by numerous Societies as well as private individuals. In addition, many of the *Journals* and *Proceedings* of Societies to which the student would desire to refer are long since out of print, and many of them fetch a very high price indeed. Such are the *Chinese Repository*, the *Oriental Repertory*, Logan's *Journal of the Indian Archipelago*, and many others that could be named. In London these can be consulted at the British Museum, at the libraries of the India Office and the Royal Asiatic Society, and perhaps elsewhere; but this is of little service to the student elsewhere in the British Islands, and still less to one who is working in the very field itself, in the Malay Peninsula, Java, Borneo, Bangkok, or China. Occasionally, an enterprising Society or publisher may republish some of these old papers, but this is not often done, for the number of immediate buyers is necessarily small, and the return therefore slow and doubtful.

Recent events in various parts of Further India, including in this term that part of Asia west of Burmah and south of China, have attracted the public mind to these regions. Accordingly, the Straits Branch of the Royal Asiatic Society, which has its seat at Singapore, decided to publish a first instalment of papers relating to Indo-China, but mainly to the Malay Archipelago, scattered about in various periodicals now beyond the reach of most students, and out of the question for those who are unable to consult large libraries. A selection of papers was made by officers of the Society in Singapore; these were carefully edited by Dr. Rost, the Librarian of the India Office, and the work was fortunate in being placed in Messrs. Trübner's Oriental Series—a series of works which, whether we regard individual excellence or the range of Oriental knowledge which it embraces, stands unrivalled in the world, for in every direction it forms the high-water mark of European study of the East. The present volumes include selections from the papers published in Dalrymple's *Oriental Repertory*, the old *Asiatic Researches*, and the *Journal* of the Asiatic Society of Bengal. It may be hoped that the Society will feel able and willing to continue the issue of similar selections from other sources. The papers commence about 1808, and the latest are dated about 1860, and they embrace almost every subject of interest relating to the East. Some of the earlier reports are now of merely historical interest, such as Topping's account of Keddah, Barton's surveys and description of Balambangan, and the history of the formation of the East India Company's establishment at Penang. But others are of more value. There are numerous descriptions of various economic products, as

the gum vine of Penang, the caoutchouc vine of Sumatra, and metals in the Malay Peninsula. In philology and ethnology we have a paper on traces of the Hindu language amongst Malays (by Marsden); Dr. Leyden's famous paper on the languages and literature of the Indo-Chinese natives, the alphabets of the Philippine Islands, &c. There are several papers on geology and natural history. Two of the latter are catalogues of the Mammalia and reptiles inhabiting the Malay Peninsula, by Dr. Cantor; while a third is a catalogue of the botanical collection brought home by the same naturalist in 1841. Another paper re-published has a peculiar interest, in view of the surveys undertaken by the French two years ago in the Krau isthmus for the purpose of cutting a canal. This is a report by Capts. Fraser and Forlong on a journey from the mouth of the Pakchan River to Krau, and thence across the isthmus to the Gulf of Siam. In the 16th paragraph of that report they urged that the Bay of Bengal could be connected with the China Sea by cutting through the isthmus at comparatively little expense. They enter into calculations showing how easily this could be done, the advantages of the route, &c. These calculations of distance, cost, &c., are exceedingly elaborate, and show that the two officers entered thoroughly into the matter.

It will thus be seen that the volumes offer much of interest to several classes of students, and we repeat the hope that the Singapore Society may shortly be in a position to continue the publication of further selections.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Physiological Selection and the Origin of Species

SEEING that criticisms on the theory of physiological selection are flowing through channels other than the pages of NATURE, and this in a volume larger than could at first have been anticipated, it seems desirable that I should now permit them to exhaust themselves before undertaking a further and a general reply. On the present occasion, therefore, I will only ask you to be good enough to insert the following remarks.

In order to put myself right with my critics, I should like them to remember that the paper published by the Linnean Society is designedly restricted to a preliminary statement of principles, which, it was hoped, might fulfil its avowed object of inducing other naturalists to co-operate with me in verifying the theory by observation and experiment, in the ways suggested. Such being the design, all details as to facts and references were intentionally omitted, and the same has to be said for all objections to the theory which had occurred to my own mind. All these things will require to be gone into with the utmost care, should the course of verifying inquiry eventually prove that the voice of Nature pronounces for the theory. Therefore, while I shall be thankful for all criticisms, I should like my critics to remember that they have not as yet my whole case before them. In particular, I may intimate that I should not have published even the outlines of my theory had I not been prepared for the very obvious exceptions which are taken to it by Mr. Wallace in the current issue of the *Fortnightly Review*.

I am much indebted to Mr. Francis Darwin for his reference to Mr. Belt's anticipation of my theory, for the fact that in its general form this theory has independently occurred to so distinguished a naturalist, appeals to me as an additional pledge of its probability. On the other hand, I am greatly disheartened by his further statement that he has reason to suppose his father was "familiar with the principle of physiological selection," and yet "did not regard it with any great favour." Hitherto I have been under the impression that it was a theory to which the judgment of his father would probably have inclined, and therefore I shall await with no ordinary interest the statement of his reasons for thinking otherwise, whether this be communicated through your columns or privately to myself. It only remains to add that, if Mr. Darwin will be kind enough to turn to p. 380 of my paper, he will find that I have quoted *in extenso*, and with its context on both sides, the passage from the "Origin of Species" which he extracts. But it does not appear to me that this passage furnishes any evidence that the theory of physiological selection was ever present to the mind of the writer—less evidence, for instance, than there is from a passage in one of his earliest writings that the theory of natural selection was present to the mind of Mr. Herbert Spencer.

GEORGE J. ROMANES

Geanies, Ross-shire, September 4

Actinotrocha of the British Coasts

I HAVE been reminded by Mr. T. Bolton, of Birmingham, that about three years ago I sent him living specimens of what Mr. A. G. Bourne afterwards identified as *Phoronis*. At the time I was under an impression, from hasty observation of the arrangement of the tentacular crown, and before I had seen the entire animal, that I had found a new Polyzoan allied to *Lophopus*. *Phoronis* occurs here in company with *Spio seticornis*; a solitary individual or a small group of the former, in the midst of a colony of the latter. A block of stone densely populated with these annelids is a most interesting object in a tank. To me they have proved so interesting that I believe I have spent more time over them than over any other marine organism.

I take the opportunity of calling attention to what I believe is an undescribed species of *Peridinium* that annually recurs in these waters. The form is flattish, and the outline bi-conical, having one end bifurcated, with a flagellum in the fork, and a central ciliary groove. By degrees it loses its present form, and assumes that of a spheroid.

I will gladly send specimens of either or all of these organisms to any naturalists who may wish to study them, if the cost of carriage be defrayed and the applicants not very numerous.

Sheerness-on-Sea W. H. SHRUBSOLE

A New Aerolite

ON May 28 last a farmer of Barntrup, a small town of the Principality of Lippe, in the north-west of Germany, walking in the afternoon, 2h. 30m., on the edge of a neighbouring wood, suddenly heard repeated reports like those of a gun, followed shortly after by an indistinct rumbling as of thunder. At the same time a meteorite came crashing through the leaves of a tree. The rumbling came from a south-westerly direction, the temperature was warm, the sky bright, and almost entirely cloudless.

This is the twelfth case of a meteoric fragment being found in the north-west of Germany. It is a monolith of about the size of a walnut, and weighs 17·3 grammes (specific weight = 3·495). It is covered with a black crust chipped off in places by the fall. Under this crust it is of a light gray colour and granitic substance, dotted in places with small yellow crystals, which are probably troilite or schreibersite. It has been lately presented to the Detmold Museum. L. HAEPKE

Bremen, Germany

DRAPER MEMORIAL PHOTOGRAPHS OF STELLAR SPECTRA EXHIBITING BRIGHT LINES

THE spectra of ordinary stars, whether examined directly by the eye, or indirectly by means of photography, present little variety. The comparatively few cases of deviation from the usual type are therefore particularly interesting, and the occurrence of bright lines in a stellar spectrum constitutes perhaps the most singular exception to the general rule. The brightness of the F line in the spectra of γ Cassiopeiæ and β Lyræ was noticed by Secchi. Rayet afterwards found three rather faint stars in Cygnus, the light of which was largely concentrated in bright lines or bands. The adoption at the Harvard College Observatory of a system of sweeping, with a direct-vision prism attached to the eye-piece of the

equatorial telescope, resulted in the discovery by the present writer of several additional objects of the same class. Still more recently, Dr. Copeland, during a journey to the Andes, has extended the list by the discovery of some similar stars in the southern heavens.

Among the photographic observations which have been undertaken at the Harvard College Observatory, as a memorial to the late Prof. Henry Draper, are included a series of photographs of the spectra of all moderately bright stars visible in the latitude of the Observatory. A recent photograph of the region in Cygnus, previously known to contain four spectra exhibiting bright lines, has served to bring to our knowledge four other spectra of the same kind. One of these is that of the comparatively bright star P Cygni, in which bright lines, apparently due to hydrogen, are distinctly visible. This phenomenon recalls the circumstances of the outburst of light in the star T Coronæ, especially when the former history of P Cygni is considered. According to Schönfeld, it first attracted attention, as an apparently new star, in 1600, and fluctuated greatly during the seventeenth century, finally becoming a star of the fifth magnitude, and so continuing to the present time. It has recently been repeatedly observed at the Harvard College Observatory with the meridian photometer, and does not appear to be undergoing any variation at present.

Another of the stars shown by the photograph to have bright lines is D.M. + 37° 3821, where the lines are unmistakably evident, and can readily be seen by direct observation with the prism. The star has been overlooked, however, in several previous examinations of the region, which illustrates the value of photography in the detection of objects of this kind.

The other two stars first shown by the photograph to have spectra containing bright lines are relatively inconspicuous. The following list contains the designations according to the *Durchmusterung*, of all eight stars, the first four being those previously known:—35° 4001, 35° 4013, 36° 3956, 36° 3987, 37° 3821, 38° 4010, 37° 3871, 35° 3952 or 3953. Of these 37° 3871 is P Cygni, and 37° 3821, as above stated, is the star in the spectrum of which the bright lines are most distinct.

Edward C. Pickering

PEAT FLOODS IN THE FALKLANDS

THE accompanying narratives of a singular visitation which has befallen the town of Stanley in the Falklands may be of some interest to the readers of Nature. Though the causes are so different, the effects of the bursting of a peat-bog in some respects curiously simulate those of a lava-flow. The papers have at different times been sent to Kew from the Colonial Office. It is partly in the hope that their publication may lead to some practical suggestion for dealing with the trouble that I ask for their insertion in your columns.

W. T. Thiselton Dyer

The Acting-Governor Bailey to Governor Callaghan, C.M.G.

Stanley, Falkland Islands, January 1, 1879

Sir,—I regret to have to report to you the circumstances attending an accident which happened early on the morning of November 30 last.

Just after midnight on Friday, November 29, one of the inhabitants was awakened by the continued barking of his dog, and thinking that a cow had strayed into his garden, he went outside, when to his alarm he found that his house was surrounded by a black moving mass of peat several feet in height, and travelling down the hill at about four to five miles an hour. It was not until daylight that the extent of the disaster was manifested.

The sufferers by the calamity were quite shut off from communication with the rest of the settlement, until they had cut a way for themselves through the heap of liquid peat, which everywhere surrounded their dwellings. Fortunately no lives were lost.

Immediately, when the report reached me, I proceeded to the scene of the disaster, and found the town in a worse state than it had been represented, all communication between the east and west end of Stanley being entirely cut off, except by boats. At this time there was no perceptible movement in the mass of peat which covered the ground in confused heaps, except in Philomel Street and the drain on the east side where I perceived the liquid peat moving down at a very slow rate. To get rid of this as quickly as possible, I found it advisable to turn all the water that could be dammed up, and sluice the peat whilst in a liquid state, and by this means I eventually cleared Philomel Street. On following up the course which the slip had taken, the hill presented a curious appearance. From the peat bank, down to the brow of the hill, a distance of about 250 yards, the surface-peat lay in confused heaps direct from the opening of the bog. The moving power (whether water or liquid peat it is impossible to say) travelled over the ground faster than the heavier bodies, which were left standing 3 to 4 feet above the level of the ground.

Proceeding to the top of the bog, I found a depression extending over 9 to 10 acres of ground, the edges cracking and filling up with water, and threatening another accident. I at once saw the necessity of calling upon the inhabitants to assist me in cutting a trench at the back of the hill, so as to draw off this accumulation of water, which seemed likely to float the loose peat left in the depression down into the settlement. I am glad to say that this call was heartily responded to by every man in the settlement, the gentlemen finding substitutes to take their places.

All worked for eight days in the cold and the rain, but nevertheless they were unsuccessful in carrying the trench through the bank into the bottom of the slip, owing to the soft peat welling up from the bottom and filling the trench again. Seeing that the exertions were of little avail in the present state of the bog, I did not press the settlers to continue the work that was so disheartening in its results; and as I now felt satisfied, from the great quantity of water that had been drained off, and the cutting being at a level, that this would prevent any further accumulation of water taking place in the slip, as there was no immediate danger of another accident taking place, the work was stopped, and I published the inclosed notice.

With your Excellency's permission I will, in the course of a few weeks, prepare sections of the bog and the settlement, showing a plan of drainage which will, I hope, prevent a similar accident happening again.—I have, &c.,

(Signed) Arthur Bailey

His Excellency Governor Callaghan, C.M.G.

Lieut.-Governor Barkly to Earl Granville

Government House, Stanley, Falkland Islands, June 3, 1886

My Lord,—I regret to have to report that a slip of the peat-bog at the back of the town of Stanley, similar to that which occurred in November 1878, but about 200 yards to the westward of the scene of that accident, took place last night. A stream of half-liquid peat, over 100 yards in width and 4 or 5 feet deep, flowed suddenly through the town into the harbour, blocking up the streets, wrecking one or two houses in its path, and surrounding others so as completely to imprison the inhabitants. Fortunately, as the night was wet and stormy, almost every one was within doors, and the few who were in the wrecked houses escaped in time. One child was, unfortunately, smothered in the peat, whose body has been recovered, but no other casualties are known to have occurred. An old man is, however, reported to be

missing this morning, and it is feared he may also have perished, as part of his house is almost filled with peat.

(2) The people of Stanley, as on the former occasion, showed great energy and resource in dealing with the danger, and before I myself reached the spot barriers had been erected and lanterns placed to keep the public from dangerous spots, whilst all those who had been driven from their homes had been accommodated by their neighbours.

(3) This morning bodies of volunteers were early at work, clearing the streets, so far as it was safe to do so without risk of disturbing the superincumbent mass of peat and setting it in motion again, and draining the water from it as far as was practicable. I have also employed a strong body of labourers, under experienced supervision, in the same work, and have directed the removal of all persons remaining in dangerously situated houses; and there is now little risk of further accident.

(4) The slip was caused, apparently, by the unusually heavy rains which have fallen during the last few days, and which the drains constructed by Mr. Bailey, the Surveyor, in 1878, proved insufficient to carry off. Deeper and wider cuttings will now be made, and I trust that the recurrence of any similar catastrophe may thus be prevented. The town of Stanley is, however, from its situation and the mass of peat-bog on the high ground behind it, always to some extent exposed to danger of this nature in times of unusually heavy rainfall.—I have, &c.,

(Signed) ARTHUR BARKLY

The Right Hon. Earl Granville, K.G., &c.

THE BRITISH ASSOCIATION

BIRMINGHAM, *Tuesday*

THE Birmingham meeting has been one of unusual excitement, mainly originating in the pre-arranged discussions which have taken place in several of the Sections. It is generally felt that this comparatively new feature has given new life to the Association, and ought to become general in all the Sections. At present the arrangements are somewhat crude, and the discussions are apt to become unmanageable. In some cases each of the speakers has all he means to say already written out, so that the discussion becomes merely the reading of a series of papers on a given subject. In other cases, however, at the present meeting, the discussions have been to a large extent extemporaneous. This was especially so with the joint meeting of Sections A and D to consider the subject of colour-vision, and with the discussion in Section E on Geographical Education. Probably the most lively and generally interesting discussion was that which followed Mr. Seebohm's paper on Dr. Romanes' theory of Physiological Selection. Among those who took part in this were Profs. M. Foster, Newton, and Francis Darwin. On Saturday there was a lively and instructive discussion in Section C on Pre-Glacial Man, in which Prof. McKenny Hughes, Mr. Pengelley, Prof. Boyd Dawkins, Mr. De Rance, and others took part. The address of the President, Sir William Dawson, was a great popular success, so far as he could be heard. Prof. Rücker's lecture on soap-bubbles was universally admired, the experiments being unusually brilliant. Prof. Roberts-Austen's lecture to working men, on Saturday night, on the colour of metals, was greatly appreciated by a crowded audience.

The weather has not been so good as could have been wished, so that the excursions and garden parties have been somewhat damped. The *soirée* in the highly interesting Industrial Exhibition at Bingley Hall on Thursday evening was crowded and successful. Indeed the arrangements throughout made by the Local Committee for the entertainment of visitors have given complete satisfaction; the comfort and convenience of the visitors having been provided for in every conceivable way.

At the meeting of the General Committee yesterday, it was resolved to accept the invitation to Bath for 1888. For the Manchester meeting of next year, Sir Henry Roscoe was chosen President, the meeting to begin on Wednesday, August 31. The fact of an invitation having been sent from New South Wales for 1888, has been already noticed in NATURE. The invitation came up for consideration yesterday, with the result that it was decided to send a deputation of forty or fifty representative members of the Association, to be selected by the Council in co-operation with the Sectional Committees. The New South Wales Government have offered to pay all the expenses of such a deputation, but they insist, in somewhat dictatorial terms, that the deputation shall consist only of the most eminent representatives of British science. This subsidiary meeting will take place in Sydney in January 1888, when it is hoped representatives of science from all the Australasian colonies will assemble, and with the deputation hold a meeting, which will have for its object the promotion of science in Australia, and of more intimate relations between its representatives there and here. On the return of the deputation to this country it will report its proceedings to the Bath meeting; for the Australian meeting will not be regarded as a regular meeting of the British Association. On the whole, the decision come to at the General Committee meeting appears to give satisfaction. Victoria has also sent an invitation, but agreed to retire in favour of its sister colony.

The number attending the Birmingham meeting is about 2500.

Dr. MacAlister read on Thursday last to Section A a communication from the Grenada Eclipse Expedition, announcing that excellent photographs had been taken of the eclipse, and that successful experiments with the spectroscope had been made in the northern part of the expedition by Dr. Schuster, Capt. Darwin, and Prof. Thorpe. Dr. Schuster obtained two good and two fair photographs of the corona. Good spectra of the solar prominences have been obtained, showing the bright lines of highly incandescent vapours. In this respect the result resembles that obtained in the two previous eclipses, though it was thought possible that this year, being one when sunspots are tending to a minimum, would be marked by the more continuous spectrum that bespeaks lower temperature. The bright lines were especially well marked when the slit of the spectroscope was tangential to the sun's disk, less marked when the slit was radial. Capt. Darwin was in charge of the coronagraph, an instrument by which a continuous series of photographs of the corona, before, during, and after totality, can be taken. Before and after the eclipse the photographs are taken by means of Dr. Huggins's device for mechanically shutting off the glare of the sun. The idea of Capt. Darwin's observations is to test the trustworthiness of Dr. Huggins's method. If a complete continuity appears in the series of pictures taken by what may be called the artificial and the natural methods, the confidence of solar observers in the former method will be established. The series has been duly obtained, but until the plates are closely scrutinised in England it is impossible to pronounce on the success of the test. Dr. Thorpe was in charge of an instrument prepared by Capt. Abney for the determination of the intensity of the light sent out from different parts of the corona. He has been very successful, having made no fewer than fifteen determinations.

The following is the list of grants which have been made this year by the Association:—

A—Mathematics and Physics

Solar Radiation	£20
Electrolysis	50
Ben Nevis Observatory	75
Standards of Light	10
Instructions for Tidal Observations	15

Chepstow Meteorological Observatory	£20
Magnetic Observations	40
Electric Standards	50
B—Chemistry	
Silent Discharge of Electricity	20
Absorption Spectra	40
Translation of Foreign Records	5
Nature of Solution	20
Influence of Silicon on Steel	30
C—Geology	
Volcanic Phenomena of Vesuvius	20
Volcanic Phenomena of Japan	50
Exploration of Cae Gwyn Cave	20
Erratic Blocks	10
Fossil Phyllopoda	20
Carboniferous Flora of Halifax	25
Microscopic Structure of the Rocks of Anglesey	10
Eocene Beds, Isle of Wight	20
Circulation of Underground Waters	5
Erosion of Sea Coasts	15
"Manure" Gravels of Wexford	10
Provincial Museum Reports	5
D—Biology	
Lymphatic System	25
Naples Zoological Station	100
Plymouth Biological Station	50
Granton Biological Station	75
Zoological Record	100
Flora of China	75
Flora and Fauna of the Cameroons	75
Migration of Birds	30
British Marine Area	5
E—Geography	
Batho-Hypsographical Map	25
Depth of Permanently Frozen Soil	5
F—Economic Science and Statistics	
Regulation of Wages	10
H—Anthropology	
Prehistoric Races, Greek Islands	20
British Barrows	20
North-Western Tribes of Canada	50
Racial Photographs (Egyptian)	20
Anthropological Notes and Queries	10
Total	£1300

SECTION C

GEOLOGY

OPENING ADDRESS BY PROF. T. G. BONNEY, D.SC., LL.D., F.R.S., F.S.A., F.G.S., PRESIDENT OF THE SECTION

I HAVE felt it a great honour and an especial pleasure to be asked to preside at the meeting of Section C in Birmingham. A great honour, because of the repute of my predecessors; an especial pleasure, because, as born in the Midlands, I am naturally proud of the Midland metropolis, its intellectual activity, and its commercial enterprise. Besides this, there are few towns in England where I number more friends of kindred tastes than in Birmingham. Geology especially seems to thrive in this district, and little wonder when you reckon among your residents, in addition to a host of other workers, such leaders as Crosskey, *malleus erraticorum*, Allport, who taught me how to work with the microscope, and Lapworth, to whose genius my duller mind is under constant obligation.

The addresses delivered at the annual meetings of the British Association afford a convenient opportunity for what may be termed stock-taking in some branch of science which has especially attracted the attention of the author; for a brief review of past progress; for a glance forward over the rich fields which still await exploration. We may compare ourselves to pioneers in a land as yet imperfectly known, the resources of which are only beginning to be developed. Taking our stand upon some vantage-ground at the border of the clearings, we glance forward over plains as yet untrodden, over forests as yet untracked, to consider in what directions and by what methods of investigation new lands can be won through peaceful conquest, new treasures added to the world's intellectual wealth.

I purpose, then, on the present occasion to offer a few remarks upon a branch of geological investigation which appears to me one rich in promise for future workers. The key-note of my address might be conveyed in the following sentence: "The application of microscopic analysis to discovering the physical geography of bygone ages." The ultimate aim of geological researches is obtaining answers, in the widest and fullest sense, to these two problems in the history of our globe—the evolution of life upon it, and the evolution of its physical features. In the former a host of labourers, before and since the epoch of Darwin's great book, have been employed in collecting and co-ordinating facts, and in framing hypotheses by scientific induction. In the latter the workers are fewer, but the results obtained are neither small nor unhopeful. In the past generation, men like Godwin-Austen pointed out the principles of work and gathered no small harvest, but in the present the application of the microscope to the investigation of rock-structure has facilitated research by furnishing us with an instrument of precision; this, by disclosing to us the more minute mineral composition and structural peculiarities of rocks, enables us to recognise fragments, and sometimes even to determine the source of the smaller constituents in a composite clastic rock. The microscope, in short, enables us to declare an identity where formerly only a likeness could be asserted, to augment largely in all cases the probabilities for or against a particular hypothesis, and to substitute in many a demonstration for a conjecture.

Once for all, I ask you to bear in mind that this address is mainly a recital of other men's work, so that I shall not need to interrupt its continuity by remarks as to the original observers. The subject is, indeed, one to which I have paid some attention, but I can only call myself a humble follower of such men as Godwin-Austen, "the physical geographer of bygone periods," and Sorby, who was the first to apply the microscope to similar problems, and to whom in this class of investigation we may apply the well-known saying, *Nihil tetigit quod non ornavit*.

With the deepest gratitude also I acknowlege the loan or the gift of specimens from Drs. Hicks and Callaway, from Messrs. Howard Fox, Somervail, Shipman, Gresley, Houghton, Marr, Teall, and J. A. Phillips, from Profs. Lapworth and Judd. Through their liberality I have had the opportunity of examining for myself the greater part of the materials which have already been described in the principal geological periodicals, and of adding many new slides to my own collection.

The nature of the materials of grits and sandstones has been so admirably treated by Dr. Sorby in his presidential address to the Geological Society for 1881 that I may pass briefly over this part of the subject. I will, however, add a few details in the hope of placing more clearly before you the data of the problems which are presented to us. In order to exemplify the size of the fragments with which we have to deal, I have made rough estimates of the diameters of the constituent grains in a series of quartzose rocks. Sometimes there is much variability, but very commonly the majority of the grains are tolerably uniform, both in size and shape. In a slide from the Lickey quartzite, exposed in the railway cutting at Frankley Beeches, grains, often well rolled, ranging from ·02″ to ·03″ are very common. In a specimen of Hartshill quartzite, they range from ·01″ to ·03″, but the most common size is a little under ·025″. In a quartzite from west of Rushton (Wrekin) a good many grains range from ·03″ to ·05.″ In two speciments of quartzite (white and pale grey) from near Loch Maree, the grains commonly vary a little on either side of ·02″, while in a specimen of the "fucoidal quartzite" (mouth of Glen Logan) much greater variety is exhibited, a good deal of the material being about ·01″ in diameter, but with many scattered grains up to ·03″. The grains in a pale grey quartzite from the Bunter beds at the north side of Cannock Chase range from about ·01″ to ·015″, and are very uniform. In a liver-coloured quartzite from the same locality they are about as long, but narrower and sharply angular in form. These will serve as examples of what we may call an average, moderately fine grit or sandstone. It is my impression that in a very large number of ordinary sandstones most of the grains range from about one to three hundredths of an inch. In rocks, however, to which most persons would apply the epithet "rather coarse-grained," fragments of a tenth of an inch or more in diameter are common.

It is extremely difficult to give, in general terms, an estimate

of the size of the crystalline constituents of ordinary granites, and the more coarsely crystalline gneisses. But speaking of those which enter into the composition of the ground mass, I should say that the individual quartz grains do not often exceed ·03″, and are very frequently between this and ·02″. In the finer-grained granites and more distinctly banded gneisses, and their associated quartziferous schists, about ·01″ is a common size, while in the finer schists (believed by many geologists to be later in date than the aforesaid) they range from ·002″ downwards, and do not generally exceed ·001″. Feldspar crystals, where they occur, probably do not differ very materially in area from the quartz, though they are often, as might be expected, rather longer and narrower; mica crystals, cut transversely, are often longer and usually much narrower. Of other constituents, as being either rarer or more liable to change, I will not speak in detail. The individual quartz grains, in the compact and glassy varieties of the more acid igneous rocks, are about the same size as those in an ordinary granite.

Space does not permit me to enter upon the methods of distinguishing between the materials furnished by the different varieties of crystalline schists, gneisses, and igneous rocks of similar chemical composition. For the most important of these I must refer you to Dr. Sorby's address, but I may add that there are others which it would be almost impossible to describe in words, as they can only be learnt by long-continued work and varied experience. I do not pretend to say that in the case of a grit composed of fragments of about ·02″ diameter we can succeed in identifying the parent rock of each individual, but I believe we can attain to a reasonable certainty as to whether any large number of its constituents have been furnished by granitoid rocks, by banded gneisses and schists, by fine-grained schists or certain phyllites, by older grits or argillites, or by lavas and scoria. There seem to be certain minute differences between the feldspars from a granitoid rock and from a porphyritic lava, and more markedly between the quartz grains from the two rocks. The latter can generally be distinguished from the polysynthetic grains furnished by certain schists or veins, and these not seldom one from another. Obviously the larger the fragments the less, *cæteris paribus*, the difficulty in their identification. When they exceed one-tenth of an inch the risk of important error is, I believe, to a practised observer comparatively small.

Obviously, also, the shape of the grains leads to certain inferences as to the distance which they have travelled from their original source, and as to the means of transport, but into the details of this I must forbear to enter. I will merely remind you that small angular fragments of quartz are so slowly rounded when transported by running water that, if well-rounded grains appear in large numbers in a sandstone, it seems reasonable to suppose that these are, in the main, wind-drifted materials.

Thus every rock in which the constituent particles admit of recognition and of identification may be made to bear its part in the work of deciphering the past history of the globe. Where the constituents have been derived from other rocks, we obtain some clue to the nature of the earth's crust at that epoch; where the locality whence a fragment was broken can be discovered, the nature, strength, and direction of the agents of transport can be inferred. Some idea as to the structure and surface-contour of the earth in that district, and at that time, can be formed; and thus the petrologist, by patient and cautious induction, may, in process of time, build up from these scattered fragments the long-vanished features of the prehistoric earth, with a certainty hardly less than that of the palæontologist, when he bids the dry bones live, and repeoples land and sea with long-vanished races. The latter study is in vigorous maturity, the former is still in its infancy: so much wider then is the field, so much more fascinating, to many minds, is the investigation. There are many districts which are without fruit for the palæontologist—there are few indeed which, to the petrologist, do not offer some hope of reward. The field of research is so wide that not one nor few men can gather all its fruits. It needs many workers, and it is in the hope of enlisting more that I have ventured to bring the subject before you to-day.

Materials of the Coarser Fragmental Rocks of Great Britain[1]

I proceed now to give a brief epitome of the constitution, so far as I know it, of our British grits, sandstones, breccias, and conglomerates. I shall exclude, as involving too many collateral issues, the Post-Pliocene beds, and dwell more on the earlier than on the later deposits, because the latter obviously may be derived from the former by denudation, so that it becomes the more difficult to conjecture the immediate source of the constituent particles. Further, in order to avoid controversy on certain questions of classification, or for brevity, I shall occasionally group together geological formations which I think separable.

It may be convenient, however, to call your attention to the localities at which, at the present day, granitoid rocks (many of which may be of igneous origin, but are of very ancient date), gneisses, and crystalline schists are exposed in Great Britain, as well as those where considerable masses of igneous rock of age not later than Mesozoic occur. The former constitute a large part of the north-western and central highlands of Scotland and of the islands off its west coast; they are exposed in Anglesey and in the west and the north of Carnarvonshire; they form the greater part of the Malvern Chain, and crop out at the Wrekin; they occur on the south coast, at the Lizard, and in the district about Start Point and Bolt Head; they rise above the sea at the Eddystone. It is probable that these last are the relics of a great mass of crystalline rock, which may have extended over the Channel Isles to Brittany; also, that we may link with the *massif* of the Scotch highlands the crystalline rocks of Western Ireland on the one hand, and of Scandinavia on the other. Among the indubitably igneous rocks we have granite, or rocks nearly allied to it, in Scotland, in the Lake district, in Leicestershire, and in Devon and Cornwall. Feldstones, old lavas, and tuffs of a more or less acid type occur in Southern Scotland, to some amount also in the Highlands, in the Lake district, and in various localities of rather limited extent in West-Central England, as well as in the south-west region just mentioned, while in Wales we have, in the northern half, distinct evidence of three great epochs of volcanic outbursts, viz. in the Bala, in the Arenig, and anterior to the Cambrian[1] grits and slates. In South Wales there were great eruptions at the last-named epoch and in Ordovician times. I have passed over sundry smaller outbreaks and all the more basic rocks as less immediately connected with my present purpose. It is, I suppose, needless to observe that a coarsely crystalline rock, whether igneous or of metamorphic origin, must be considerably older than one in which its fragments occur.

Cambrian and later Pre-Cambrian.—That the majority at least of the gneisses and crystalline schists in Britain are much older than the Cambrian period will now, I think, hardly be disputed by any who have studied the subject seriously and without prejudice. There are, however, later than these, numerous deposits, frequently of volcanic origin, whose relation to strata indubitably of Cambrian age is still a matter of some dispute. Therefore, in order to avoid losing time over discussions as to the precise position of certain of these deposits, or the particular bed which in some districts should be adopted as the base of the Cambrian, I will associate for my present purpose all the strata which, if not Cambrian, are somewhat older. The latter, however, exhibit only micro-mineralogical changes, and of their origin, volcanic or clastic of some kind, there can be no reasonable doubt; so that the difference in age does not appear to be enormous; that is to say, I include with the Cambrian the Pebidian of some recent authors.

The utility of microscopic research has nowhere been better exemplified than in the case of the oldest rocks of St. David's. Some authors have supposed that the base of the Cambrian series in this district has been "translated" beyond recognition, others that it has been thrust out of sight by the intrusion of granitic rock. But low down in the series, beneath the earliest beds that have as yet furnished fossils to British palæontologists, there is a well-marked and widespread conglomerate; underlying this, with apparent unconformity, comes a series of beds very different in aspect, chiefly volcanic, and beneath this a granitoid rock. The conglomerate, in places, even without microscopic examination, proves the existence, though probably at some distance, of more ancient rock, as it is full of pebbles of vein-quartz and quartzite; but in other parts it is crowded with pebbles closely resembling the feldstones in the underlying volcanic group, and in some parts becomes a regular *arkose*, made up almost wholly of quartz and feldspar,

[1] I have been obliged to exclude those of Ireland, as I have so little material from that country, and for want of space have not dealt fully with those of Scotland.

[1] I take the base of the Arenig as the commencement of the next formation, the Ordovician, which thus represents one phase of the Lower Silurian in the variable nomenclature of the Geological Survey.

closely resembling those minerals in the granitoid rock, of which also small rounded pebbles occasionally occur. One or two fragments of a quartzose mica-schist, which is not known to occur *in situ* in the district, have also been found. It is therefore evident that not only is the volcanic series somewhat, and the granitoid rock considerably, older than the conglomerate, but also that an important series of rocks, some of which were thoroughly metamorphic, was exposed in the district when the conglomerate was formed. I have very little doubt that a study of the finer-grained sedimentary Cambrian beds overlying the conglomerate will corroborate, were it needed, the conclusion which the latter justifies. Passing on to North Wales, the coarser beds in the Harlech axis, so far as they have been examined, are found to be full of fragmental quartz and feldspar, which is undoubtedly derived from a granitoid rock; some beds being made up of little else. No rock of this character, so far as I am aware, is exposed in this part of Wales, but a ridge of granitoid rock extends from the town of Carnarvon to the neighbourhood of Port Dinorwig. Through this, apparently, the great feldstone masses which occupy considerable tracts on the northern margin of the hills between Carnarvon Bay and the valley of the Ogwen have been erupted, and over this comes a series of grits, slates and conglomeratic or agglomeratic beds, overlain ultimately by the basal conglomerate of the undoubted Cambrian series. It was formerly maintained that these feldstones were only lower beds of the Cambrian metamorphosed—practically fused by some "metapeptic" process. This notion, however, was quickly dispelled by microscopic examination. The overlying conglomerate is often crowded with pebbles, identical in all important respects with the feldstone itself, which also presents many characteristics of a lava flow as opposed to an intrusive mass, and is no doubt an ancient rhyolite now devitrified. There is some difference of opinion among the geologists who have worked in this district as to the exact correlation of various gritty, conglomeratic or agglomeratic beds which succeed the feldstone, as is only natural where disturbances are many, and continuous outcrops generally few. But all agree on the existence of a series, into which volcanic materials enter largely, between the above-named basal Cambrian conglomerate and the feldstone. In this, then, and in the basal conglomerate we have again and again more or less rounded fragments of old rhyolitic lavas. We have numerous and varied *lapilli*, probably of like chemical composition. We have grits which are largely composed of quartz and feldspar, resembling that in the granitoid rock, together with fine-grained quartzose schists and bits of rhyolite, all mingled together. We have also occasionally, as in the Cambrian conglomerate near Llyn-Padarn, pebbles of the granitoid rock. Further, the basal conglomerate, as near Moel Tryfaen, is sometimes crowded with fragments of gritty argillites. Fine-grained schists, as will be noted, seem to be rare in this district, but, as such rocks occur *in situ* in the Lleyn peninsula, they will probably be discovered more abundantly when the Cambrian conglomerate is examined further in that direction.

Fine-grained micaceous, chloritic, and other schists occupy a considerable portion of Anglesey, and in the neighbourhood of Ty Croes there is an important outcrop of granitoid rock. The former were once regarded as metamorphosed Cambrian, the latter as granite which aided in the metamorphism at the end of the Ordovician period. In Anglesey the earlier Palæozoic rocks are not generally rich in fossils, so that it is sometimes difficult to settle their precise position. The oldest beds which have been thus identified have been placed in the Cambrian (Tremadoc), but some experts have doubted whether quite so low a position can be assigned to them. Hence the exact age of the oldest Palæozoic beds in this island is uncertain, as also whether the basal conglomerates near Ty Croes are of the same age as those in Carnarvonshire. This, however, is certain, that some of the Anglesey grits above the basal conglomerate are largely made up of quartz and feldspar derived from a granitoid rock. Others contain numerous fragments of very fine-grained schists, like those so abundant in the island, and the conglomerate contains pebbles sometimes full two inches in diameter, absolutely identical with the rocks in the adjacent granitoid ridge (the foliated structure distinctive of some parts of it having been even then assumed), together with various metamorphic rocks, some green schistose slaty rocks, and some reddish slates. The last two were, I doubt not, cleaved before they became fragments; probably these were derived from the hypometamorphic series, which Dr. Callaway has described, and which also contains pebbles of the granitoid rocks. Fragments of the characteristic fine-grained schists are, so far as I at present know, less common among the Anglesey grits and conglomerates than one would expect, perhaps owing to their comparative destructibility; but I have found them occasionally and suspected their presence more often. Hence there can be no doubt that older crystalline rocks have very largely contributed to the formation of at least the coarser members of the lower Palæozoics of Anglesey.

Passing now to Central England, we come to regions which may be regarded as almost the exclusive property of your local geologists. The Hollybush sandstone on the flanks of the Malvern is, no doubt, largely composed of the finer debris of the older rocks of that chain, but the Malvern hills are only an unburied fragment of a vastly larger area of crystalline Archæan rock. This is just indicated some seven miles further north in the Abberley Hills. It crops up at either end of the Wrekin, and for a little space near Rushton, but in the later fragmental rocks of the district we have abundant proofs of its existence. The central part of the Wrekin is composed of volcanic rocks, rhyolites of varied kinds, with agglomerates; these were once regarded by our highest authorities as greenstones intrusive in beds of Ordovician age, but Mr. S. Allport has taught us their true nature, and Dr. Callaway has proved their far greater antiquity. Similar rocks are to be found elsewhere in the neighbourhood of the Wrekin, and in the district farther west. We cannot affix a precise date to the volcanic outbursts of the Wrekin, but we can prove that they are not newer than the quartzite which fringes the hill, as it contains fragments of the perlitic and other glassy rocks of the apparently underlying series. This quarzite is certainly much older than the newer part of the Cambrian, and pebbles of rhyolites, resembling those of the Wrekin, occur in the indubitable Cambrian beds farther west. For instance, a grit at Haughmond Hill is quite full of fragments of volcanic rock, many of these scoria; another suggests the derivation of some of its materials from a mica-schist, while, according to Dr. Callaway, the conglomerates and grits of the Longmynds (which form the main part of the mass) are largely derived from older rocks, the former being crowded with pebbles of purple rhyolite, quartz, feldspar, mica, and occasional bits of mica-schist. A most interesting conglomerate, apparently older than the quartzite, occurs at Charlton Hill. This contains more or less rolled fragments of grits, quartzites, and argillites, looking in several cases as if they had undergone, before being broken off, the usual micro-mineralogical changes. It contains also fragments of rhyolite and many of coarse granitoid or gneissoid rocks of Malvernian type, besides numerous grains of quartz and feldspar of a like character. Finer-grained gneissoid rocks and schists, micaceous, hornblendic, or chloritic, are present in fair amount. The last bear some resemblance to the Rushton rocks, and remind me strongly of rocks which occur in the Highlands and in the Alps, apparently not in the lowest part of the Archæan series. Some also resemble the Anglesey schists. The quartzite itself is largely made up of grains of quartz which appear to me to have been derived from old granitoid rocks. Occasional grains, however, suggest by their composite structure derivation from a quartzose rock of finer texture, and, as already said, bits of the Wrekin rhyolite sometimes occur. The same is true of the Lickey quartzite, in regard to all three constituents, in which an occasional grain of microcline, very characteristic of old granitoid rocks, has been observed. The quartz grains in this and in the former rock are occasionally very much rounded. The Lickey quartzite has lately been shown by Prof. Lapworth to overlie rhyolitic rocks, and it is much older than the lowest Silurian. Not improbably it is of the same age, and was once connected with that of the Wrekin district. The Hartshill quartzite, near Nuneaton, has a similar composition, is below Cambrian, and overlies some rhyolitic rocks. Thus these insulated areas prove the existence of an old fragmental series, which is largely composed of materials derived from pre-existing and much more ancient Archæan rocks. It is difficult to assign a date to the unfossiliferous rocks forming the rugged hills of Charnwood Forest, but, as they have been affected by very ancient earth-movements, and there is nowhere any valid evidence of volcanic activity in the true Cambrians, they may be assigned with most probability to the antecedent epoch, which seems to have been one of great disturbance. Microscopic examination has shown that materials of volcanic origin enter largely into the composition of these Charnwood rocks, even the most finely grained; but besides occasional fragments of slaty rock in the breccias, for which a high antiquity cannot be asserted, we find

some pebbles of vein-quartz and two or three beds of quartzite. The grains in these appear to have been derived from old granitoid rocks, and not from the porphyritic rhyolites of the district. In one case at the Brande, they are most conspicuously rolled, and this has happened, though less uniformly, in a grit from near the ruins, Bradgate, which also contains grains of compound structure. In conclusion, I must briefly notice the so-called Torridon sandstone of North-Western Scotland, which is in many respects invaluable to the student. That it is not later than the base of the Ordovician is indisputable; that it is underlain by and derived from a mass of Archæan rocks—gneisses, more or less granitoid, with occasional schists—is universally admitted. Its coarser basement beds are crowded with fragments of the underlying gneisses and schists, and since the epoch of their formation no material change has taken place in either the one or the other. The finer beds, though other materials occasionally occur, are largely, sometimes almost exclusively, composed of grains of quartz and of feldspar identical in every respect with those in the underlying series. It may be a fact of some significance, for it agrees with what I have elsewhere noticed in very old fragmental rocks, that the feldspar appears to have been broken off from the parent rock while still undecomposed, and in many cases is even now remarkably well preserved. It would seem, therefore, as if the denudation of the granitoid rock had been accomplished without material decomposition of its feldspar, but I must not allow myself to digress into speculations on this interesting and suggestive fact. While referring to this district I may mention the quartzites, though, strictly speaking, they are Ordovician in age. These in some cases consist all but exclusively of quartz grains derived from the Archæan series, which, however, are generally smaller than those in the Torridon; it would seem as if the feldspar of the parent rock had either decomposed *in situ*, or had been broken up in consequence of the longer distance from the source of supply. This quartzite is sometimes of singular purity, containing little or no earthy material, and only rarely a flake of mica or a grain of feldspar, tourmaline, or epidote (?).

Ordovician-Silurian.—In regard to the earlier of these formations I am better acquainted with the volcanic than with the non-volcanic fragmental beds. Still, so far as I have seen, we find among the latter frequent indications of a supply of materials from regions of crystalline as well as of ordinary sedimentary rocks. The quartzite of the Stiper Stones (possibly earlier than the Arenig) appears to have derived most of its grains from granitoid rocks, and probably the same is true of many of the coarser beds in the Caradoc group of Shropshire and Eastern Wales. The Garth grit of Portmadoc appears to have derived much of its quartz from a like source as the Stiper Stones, but it also contains bits of a fine-grained quartzose schist and of older clastic rocks. A grit from the Borrowdale series of Chapel-le-dale contains, in addition, bits of old andesite and probably diabase, with fragments of a rather granitoid gneiss and quartzose schists. Fragments of crystalline rock, both small and large, abound in the Upper Llandovery beds at Howler's Heath, at Ankerdine Hill, in the Abberley district, on the west flank of the Malverns, and at May Hill, thus indicating that early in Silurian times far greater outcrops of crystalline rock existed than are now visible west of the Severn. Mr. W. Keeping (*Quart. Journ. Geol. Soc.* vol. xxxvii. p. 149, &c.(calls attention to the abundance of fragments of quartz, feldspar, and mica in the "greywackes" of the Aberystwith district, which give the rock sometimes quite a granitoid appearance, and adds that, in his opinion (*ibid.* p. 150), "the abundance of feldspar crystals, so general in the Silurian rocks (Upper Silurian of North Wales, South Wales, and the Lake district), points to the neighbouring presence of a vast mass of early, perhaps primæval, igneous rocks as the great source of sediment supply in Silurian times." What I have seen of the Denbigh grit of North Wales and of the Coniston beds of the Lake district confirms this conclusion. It is true that some of the material may have been supplied by Ordivician volcanic rocks, and that the quartz grains in the specimens which I have examined are not large. But we must remember that the latter can hardly have been furnished by the lavas of the Lake district; and those of North Wales, though richer in silica, do not, so far as I know, generally contain large quartzes. These, indeed, may have been derived from the denudation of Cambrian rocks, but I should doubt the sufficiency of such an explanation. In one specimen, a Denbigh grit from Pen-y-glog, near Corwen, there occurs, besides one of smaller size, a fragment about ·1" in diameter, exhibiting a micrographic arrangement of quartz and feldspar. In Cornwall, among beds which are almost certainly Ordovician or Silurian, we find similar evidence of derivation from much more ancient rocks. The conglomerates of the Meneage district contain, in addition to quartzites, greywackes, and other old sedimentary beds, abundant fragments of a moderately coarse-grained granitoid rock, and occasionally a hornblendic rock similar to the well-known Lizard schist. A series of specimens which I have examined microscopically shows, in addition to compact igneous rocks, apparently volcanic, quartz grains probably derived from granitoid rock, various fine-grained schists and schistose argillites or phyllites, quartzites, grits, and other older clastic rocks. One fragment of schist contains little eyes of feldspar, and in general structure reminds me of some in the so-called "Upper Gneiss" series of North-Western Scotland. Another, a fine-grained mica-schist or a phyllite, exhibits a cleavage transverse to the rumpled foliation.

A rich harvest probably awaits the explorer in the "greywackes" of the southern uplands of Scotland. A "Lower Silurian" conglomerate from Kingside, Peebles-shire, contains numerous fragments of igneous rocks, probably of volcanic origin, and bits of granitoid rock, with some which are either very old quartzites or perhaps vein-quartz. These have been crushed and re-cemented before being detached from the parent rock. The basement conglomerate of the Craig Head limestone group (Llandeilo-Bala) is full of rounded fragments of volcanic rocks. These, as in the last-named case, exhibit considerable variation; the majority, however, are probably andesites, and perhaps in one or two cases even basalts. A Middle Llandovery conglomerate from near Girvan is largely made up of fragments which appear to have been derived from very ancient quartzose rocks. The greywacke of rather later age from near Heriot, Edinburghshire, contains, with numerous volcanic fragments, and a little argillite, a few bits of fine-grained quartz-schist, together with grains of quartz and feldspar, suggestive of derivation from a more coarsely crystalline rock.

Old Red Sandstone and Devonian.—It is, I believe, indisputable that when the Old Red Sandstone of Scotland was formed a great period of mountain-making had ended and one of mountain-sculpture was far advanced. The conglomerates are often full of fragments of the crystalline rocks of the Highlands, and no doubt the sandstones derived their quartz grains from the same source. In the southern half of the country, however, as is well known, volcanic materials, more or less contemporaneous, play an important part. I have not been able to examine closely the Old Red Sandstones of England and Wales, but their frequent near resemblance to the sandstones of Scotland suggests a similar derivation. True, the materials may have been sifted from older clastic rocks, but there is nothing specially to suggest this, and the abundant pebbles of vein-quartz, which I have seen in one or two localities, seem rather more favourable to the other hypothesis. I have only examined microscopically a very few specimens of Devonian grit, all from the south side of the country. These certainly seem to have derived their materials, in part at least, from crystalline rocks, both granitoid and schists of finer grain; one specimen also apparently containing some bits of hypometamorphic rock.

Carboniferous.—In Scotland some of the basement beds of this series so closely resemble the Old Red Sandstone that no further description is needed, and the same remark may be made of the very few overlying sandstones which I have carefully examined. In the North of England the basement conglomerates, so far as I have seen them, are made up of earlier Palæozoic rocks, but for many of the great masses of sandstone which occur in the series a source of supply is not so easily found. Dr. Sorby, who has made a special study of the Millstone grit of South Yorkshire, tells us that it is formed of grains of quartz and feldspar, apparently derived from a granite, and contains pebbles, sometimes an inch or so in diameter, of vein-quartz, of hard grits, of an almost black quartz-rock or quartz-schist, and of a non-micaceous granite. He also notes one fragment of a greenstone, and another either of a fine-grained mica-schist or of a clay-slate. The granite, he states, more resembled those of Scandinavia than any one now visible in Britain, and the bedding indicated a supply of materials from the north-east. In the Millstone grit near Sheffield he says that the grains appear to be but little worn, as if they had not been drifted from far. A few also appear to have been derived from schists. From what I have myself seen, I anticipate that Dr. Sorby's conclusions may be extended to most of the other coarser Carboniferous clastic beds of Northern England, except that, perhaps, as was inferred by Prof. Hull,

another important, if not the principal, source of supply must be sought on the north-west. The materials of the basement conglomerates and grits in North Wales appear to be either Palæozoic rock or vein-quartz and an impure jasper; but a microscopic study of carefully selected specimens, especially from Anglesey, might produce interesting results. In Central England, as the Old Red Sandstone is commonly absent, and, if present, must have been speedily buried, we should naturally look further afield for the materials of the Coal-Measure sandstones and Millstone grit, where it occurs. But probably we shall be right in including this, as indicated by Prof. Hull, with the northern district. He also points out that in the south-western part of England and in South Wales there is good evidence that the materials have been brought by currents from the west. I have only examined one specimen from this region, but it has proved very interesting. It is from a Carboniferous grit near Clevedon, in Somersetshire. About one-third of the rock consists of quartz grains which I should suppose derived from schists or gneisses of moderate coarseness; quite another third of fragments of a very fine-grained micaceous schist, about ·03″ long. It is possible that these may be phyllites, but I think it far more probable that they are true schists. They are very like some of the more minutely crystalline schists of Anglesey, and it is evident in some cases that the rock had been corrugated subsequent to foliation. This grit also contains a few bits of feldspar and flakes of mica. I must not forget to mention some curious boulders which have been discovered occasionally in actual coal-seams. Through the kindness of Mr. Radcliffe I have been able to examine some specimens found at Dukinfield Colliery. They are hard quartzose grits and quartzites, bearing a general resemblance to sundry of the earlier Palæozoic rocks. One of the latter is as compact and clean-looking as the well-known quartzite of the North-Western Highlands. Besides quartz, and perhaps a little feldspar, it contains a small quantity of iron-oxide (?), two or three flakes of white mica, a grain or two of tourmaline, and of a mineral resembling an impure epidote. A similar quartzite has been found by Mr. W. S. Gresley in a coal-seam in Leicestershire, and I have described another from the "thirteenth coal" at the Cannock Chase Colliery. In each of these quartzites the two minerals last named may also be detected.

Before quitting the Carboniferous series I must call attention to some interesting grits which during the last few years have been struck in deep borings. In the London district a red sandstone, in some places conglomeratic, has been found underlying sundry members of the Mesozoic series. Some have thought this of Triassic age, but inasmuch as it is very doubtful, as we shall presently see, whether the coarser beds of the Triassic formations extended so far to the east, and the dip of the red beds in the well at Richmond agrees better with that of the Palæozoic rocks in other parts of the buried ridge, I think these sandstones more probably older than any part of the Mesozoic series, perhaps not very far away from the base of the Carboniferous. In the boring at Gayton, in Northamptonshire, Lower Carboniferous rocks were succeeded by reddish grits and sandstones. The finer beds much resembled the ordinary Old Red Sandstone, and, like it, suggested a derivation from fairly coarse-grained crystalline rocks. But of the origin of one rock, a quartz-feldspar grit, there can be little doubt. I may briefly describe it as very like the Torridon sandstone of Scotland, except that the cement is calcareous. I do not, indeed, claim for it a like antiquity, for I think it far more probably about the age of the lowest part of the Carboniferous series; but it, too, must have been derived from granitoid rocks. While some of the grains are fairly well rounded, others, especially of feldspar, as in the Millstone grit of South Yorkshire, do not seem to have travelled very far.

Permian.—The sandstones of the northern area belonging to this formation do not, as far as I have been able to ascertain, afford us much information. Quartz grains, of course, abound, but as they are rather small, it is not possible to be sure whether they have been primarily derived from a granitoid rock or a schist. The former, however, appears to me the more probable source. They also contain fragments of feldspar still recognisable, flakes of mica, and possibly a little schorl. The frequent occurrence of crystalline quartz as a secondary formation in these sandstones is a point of much interest, but has no relation to my present inquiry. The breccias near Appleby, Kirkby Stephen, &c., which I have not seen, indicate that at this time not distant masses of Carboniferous limestone, and of earlier Palæozoic rocks, were undergoing denudation; but it appears to me improbable that the finer materials of the sandstones were furnished by any rocks in the vicinity.

The Permians of the central area offer a rich field for future work. For the materials of the sandy beds I should conjecture a distant source, but for the pebbles in the conglomerates, and the fragments in the breccias, we need not travel very far afield. The Lower Carboniferous Measures contributed limestone and chert, the former being especially abundant in the conglomerates, but the "vein-quartz, jasper, slates, and hornstone," mentioned by some observers, indicate that yet earlier rocks furnished their contingent, while of the igneous materials I will speak directly. I shall pass very briefly over the breccias, so well displayed, for instance, on the Clent and Lickey hills, at no great distance from this town, because I trust we shall have presented to us, in the course of this meeting, a sample of the rich harvest which is awaiting explorers. Earlier investigators looked towards Wales for the origin of these fragments; we shall, I believe, learn that the majority are more probably derived from rocks, which, though now almost hidden from view, exist at no great distance. Some of the more compact traps may have come from the old rhyolites, which, by the labours of your geologists, have been detected *in situ* beneath the Lickey quartzite, while we may venture to refer the "red syenite" and "red granite" to outcrops of crystalline rocks of Malvernian age. These breccias have been regarded as proving the existence of glaciers in the Lower Permian age. It is, of course, possible that floating ice has been among the agents of transport, but after carefully examining the specimens in the museum of the Geological Survey on which glacial striæ are asserted to occur, I am of opinion that the marks are due to subsequent earth-movements. On only one specimen did I recognise glacial striation, and this pebble is so different from the rest that I think it must have come from drift, and not from the Permian beds.

No less interesting are the Permian breccias of Leicestershire. These have attracted the attention of an indefatigable local geologist, Mr. W. S. Gresley, and to his kindness I am indebted for the opportunity of examining both rock specimens and slices. As might be expected, fragments, which I have no hesitation in referring to the Charnwood series, are not wanting, though hitherto they have not occurred in any abundance; but perhaps the most interesting member is a tolerably hard conglomerate, containing rather abundantly pebbles of a speckled grit and of a compact "trap." Microscopic examination of this conglomerate, which varies from a fairly coarse puddingstone to a grit, shows that the above-named speckled grit is composed of small and rather angular fragments of quartz, associated with grains of brownish and greenish material, which may be in some cases decomposed bits of a rather basic lava, in others possibly a glauconite of uncertain origin. But the "trap" pebbles are yet more interesting. These are the more numerous, and are commonly well rolled. They probably belong, roughly speaking, to one species, but exhibit many varieties. In a single slide I have seen at least six, perfectly distinct. Some are indubitably scoriaceous, others full of microliths of a plagioclastic feldspar, others almost black with opacite, others mottled brown devitrified glasses, more or less fluidal in structure. Probably they belong to the andesite group, with a silica percentage not very far away from sixty. In none have I observed any signs of crushing or cleavage, so that I cannot refer them to the Charnwood series, but conjecture that they are relics of volcanoes later in age than the great earth movements which affected that series, though I cannot connect them with the more basic post-Carboniferous outbreaks of which we have indications at Whitwick and elsewhere. Quartz grains also occur, and some of these exhibit a rather peculiar "network" of cracks which is characteristic of this mineral in the rocks of Peldar Tor, Sharpley, &c., and one such grain is attached to a fragment of minutely devitrified rock. Hence, as shown by larger fragments, the Charnwood series has contributed to the materials of this conglomerate, but the more abundant appear to have been derived from volcanic vents, the locality of which is at present undiscovered.[1]

Trias.—The Bunter beds and the lower part of the Keuper consist of more or less coarse materials, while in the remainder of the latter such deposits are rare and local. Hence it is evident that after the deposition of the Keuper sandstones a very different set of physical conditions prevail. The lower series consists of sandstones and conglomerates; these beds occur in

[1] I pass by the interesting pebbles of hæmatite, which have received special attention from Mr. Gresley.

considerable force on the eastern side of the Pennine Chain, have a great development in Lancashire and Cheshire, and thin away towards the south-east, almost disappearing in eastern Leicestershire and in Warwickshire. As the Trias is followed southwards, along the valley of the Severn, the Bunter in like way dies out, while the Keuper marls may be traced on into Somersetshire and Devon. In that region also there is a grand development of the lower and coarser members. As might be expected, there are considerable differences between the lower Triassic deposits of the northern and southern areas, so that it will be convenient to speak of them separately. The northern group, as is well known, is separable in the Midland and north-western district into the Lower Bunter sandstone, the Pebble-beds, and the Upper Bunter sandstone, over which come, more or less unconformably, the Keuper sandstones. Pebbles are either absent from, or very rare in, every part of the Bunter except the pebble-bed, and are generally small and scarce in the Keuper sandstones, except in the basement breccias. It will be convenient to make a few remarks on them before dealing with the associated sands and sandstones. The pebbles in the Bunter conglomerate are most abundant, and generally attain the largest size in the Midland district. Towards the north-west, though the conglomerate attains a thickness of more than 500 feet, pebbles are rarer and smaller, and this, I believe, is also the case in Yorkshire, though the thickness of the deposit is not so great. I can, however, answer for the occurrence of pebbles of fair size and in considerable abundance for some distance to the north of Retford. In the Midland district they are very frequently from about 2″ to 4″ in diameter, though smaller are intermingled and occasionally some of large size; these attain in certain localities to a diameter of 6″, or even a little more. The majority, as far as I know, are well rounded. In this district many different kinds of rock are found in the conglomerate; the most abundant are quartzose—vein-quartz, quartzites, and hard grits or sandstones. Besides these we find chert and limestone from the Carboniferous series, various fossiliferous rocks of Silurian, Ordovician, and possibly Cambrian age, with mudstones and argillites, more or less flinty, of uncertain date. Feldstones, using the term in a wide sense, are not rare, and granites or granitoid rocks sometimes occur. These, however, together with the scarce fragments of gneiss and schist, are usually very decomposed. A hard quartz-feldspar grit, sometimes very like a binary granite, may be found, and I have noticed a peculiar black quartzose rock of rather schistose structure. As the lithology of the Bunter conglomerate has already attracted the notice of more than one author, I shall restrict myself to a brief mention of its more salient features. The most abundant rock is a quartzite, frequently so compact as to give a rather lustrous sub-conchoidal fracture, in which the individual grains can be with difficulty distinguished. In colour it varies mostly from white to some tint of grey, but is occasionally "liver-coloured." Rather obscurely marked annelid-tubes are the only organic indications which I have observed in these quartzites, and these are very rare. Under the microscope the rock consists chiefly of quartz fragments, of various forms in different specimens, with an occasional fragment of feldspar (sometimes, I think, silicified), a flake of white mica, a grain of tourmaline, and of an impure epidote (?). As a rule it is easy to distinguish this quartzite from the other indurated arenaceous rocks which occur in the conglomerate, especially from those containing fossils.

The above-described quartzites differ in appearance both macroscopically and microscopically from those of Hartshill, the Lickey, and the Wrekin district, but they closely resemble the most compact variety, which I have already described as occurring in boulders in coal. They have also an extraordinary likeness to quartzite pebbles in Old Red Sandstone and Lower Carboniferous conglomerates of Southern Scotland and to the quartzites of the Northern and Western Highlands, already described, a liver-coloured variety of which, as I have been informed, occurs in the island of Jura. These quartzite pebbles, to my knowledge, may be traced into Lancashire on the one side of the Pennine Chain and to beyond Retford on the other. The quartz-feldspar grit consists mainly of quartz and feldspar, obviously the debris of granitoid rock. I have found it at various localities on the northern margin of Cannock Chase, and have received specimens from the Bunter beds near the Lickey and near Nottingham. The rock, macroscopically and microscopically, presents an extraordinary resemblance to the Torridon sandstone of North-West Scotland, and differs from every other rock which I have seen *in situ* in any other part of Britain. The nearest approach to it is the quartz-feldspar grit, already mentioned as having been struck in the Gayton boring, Northamptonshire, but this has a calcareous cement. The feldstones vary from micro-crystalline to glassy rocks more or less devitrified, some being slightly scoriaceous. They may be classified lithologically as quartz-felsites, rhyolites (more or less devitrified), quartz-prophyrites, porphyrites, and old andesites. Some specimens contain a considerable amount of tourmaline, and I have seen this mineral in the vein-quartz pebbles. It also occurs rather abundantly in a very hard, black quartzose grit. I have received varieties of feldstone, which I have found on Cannock Chase, from the Bunter beds of the Lickey and from Nottingham. In Staffordshire pebbles of granitoid rock, gneiss, and schist are not only rare, but also generally too rotten to admit of examination; but I found a few months since, in the conglomerate at Style Cop, near Rugeley, two pebbles of a whitish gneiss, which appeared to me to indicate a secondary cleavage-foliation, such as may be observed in many parts of the Scotch highlands. The black quartz-schist already mentioned exhibits a peculiar "squeezed-out" structure, which ordinarily indicates that the rock has undergone great pressure.

The sandy matrix and associated sandstones of the conglomerate beds, together with those of the Upper and Lower Bunter, and of the Lower Keuper, consist mainly of quartz grains, most of which appear to have been derived originally from granitoid rocks. They are often more or less angular, but at certain horizons, as described by Dr. Sorby, Mr. Phillips, Mr. G. H. Morton,[1] and others, well-rounded grains are so abundant as to suggest an exposure to the action of the wind. They are often stained red with iron peroxide, and mixed with more or less earthy matter. In Cheshire and Lancashire recognisable grains of felds ar have been noticed by Mr. Morton and others, and probably this mineral is, in most cases, the source of the argillaceous constituents which are often intermingled with the quartz grains. Flakes also of white mica are sometimes rather common. So far as I have been able to judge, distinct grains of rolled feldspar are commoner in the north-western district than in Staffordshire, where, however, mica-flakes are sometimes rather abundant.

The Keuper sandstone seems to me to differ from the above only in the general absence of the red colour, and in a more even bedding, especially towards the upper part (the waterstones), where they are interbedded with the marls. The appearance of these last suggests that the currents were gradually losing strength, and only capable of transporting the finer feldspathic detritus with occasional tiny plates of mica.

The lithology of the lower part of the Trias in the southern area is as yet imperfectly worked out, and a rich harvest awaits the student. My own knowledge of it is but superficial, so that I must pass it by with a brief notice. The great beds of breccia, so finely exposed on the South Devon coast, are crowded with fragments, sometimes of large size; these have clearly been derived from the older rocks which are still in part exposed to the west and south-west, and probably had once a much greater extension in the latter direction. Fragments of Devonian limestone, grits, and slate, together probably with other Palæozoic rocks, earlier and later, are mingled with granites, resembling those of Cornwall and Devon, and many varieties of more compact igneous rock. The fossiliferous quartzite pebbles which occur mingled with others in the Trias at Budleigh Salterton, have been discussed by the late Dr. Davidson in an exhaustive memoir ("British Fossil Brachiopoda," *Mem. Palæont. Soc.* vol. iv. p. 317). He refers the majority of the fossils obtained from them to the Lower Devonian age, but a few are Caradoc, and four occur in France in beds which are either Llandeilo or perhaps a little older. As the first two formations are represented, lithologically and palæontologically, on the opposite side of the Channel in France, and the third is at present only known to occur in the *Grès Armoricain* of that country, he thinks it probable that these pebbles have been derived from rocks which are now concealed beneath the waters of the Channel. It may then, I think, be taken for granted that land to the west and south-west has supplied the materials of the Lower Trias of the southern district of England, and I may add that there is every reason to believe that outliers of the formation itself still exist beneath the sea.

The so-called dolomitic conglomerates, which occur chiefly in

[1] In an excellent paper published in the *Proceedings* of the Liverpool Geological Society, vol. v. p. 52.

Somersetshire, have been so fully worked out by Mr. Etheridge and Mr. Ussher as to require but a passing notice. It is evident that they differ somewhat in date, though probably all may be referred to the age of the Keuper, and that they are local breccias or conglomerates formed around the margin of islands or on a continental coast-line during a gradual subsidence and in comparatively quiet waters.

Jurassic.—Coarse detrital material is not very common in the Jurassic series. The limited Rhætic beds indicate a transition from the peculiar physical conditions of the Keuper to the marine conditions of the Lias, and the sediment in them was probably derived from the same source as the Keuper marls. Great clay beds also occur, as is well known, throughout the Jurassic series; and the sandstones, so far as I have been able to examine them, do not enable me to offer any suggestions as to their origin. Probably some of the grains were originally derived from granitoid rocks, but they may have been directly obtained from other sandstones. A grit, however, in the estuarine series of the lower oolites of Yorkshire (Mr. Phillips's collection) looks as if it might have been partly derived from a schist, but as this is the only rock from the northern area which I have had the opportunity of minutely examining, it would be imprudent to speculate.

Neocomian-Cretaceous.—I have examined very few specimens from the fresh-water Neocomians of the south of England, but, so far as I have seen, I should think it probable that the quartz had been derived from old crystalline rocks, though perhaps not immediately. The same remark applies to the sands of the upper and marine series, which, in one instance at least, exhibit exceptionally rounded contours.[1] Among these, however, conglomeratic beds occur which have already attracted some attention. It is obvious that no small part of the materials, as at Farringdon, Potton, and Upware, has been derived from fossiliferous secondary rocks of earlier date. There are also pebbles of vein-quartz and quartzite which, however, may have been obtained by the denudation of Triassic rocks. The "Lydian stone," which is abundant in angular or subangular fragments at Potton and Upware, is for the most part chert from the Carboniferous Limestone, or in some cases from Jurassic rocks, but a few specimens may be flinty argillites, and thus of greater antiquity. One or two pebbles of older Palæozoic rock have been found, and a hard quartz grit has occurred, containing among its grains minute acicular crystals, probably of tourmaline. Potton has furnished one or two pebbles which appear to be a devitrified pitchstone, and a large pebble of porphyritic quartzfelsite has been sent to me by Mr. Willet from Henfield (Sussex). These conglomerates, together with others in the Upper Neocomian of England, have been so fully described by Mr. Walter Keeping (*Geol. Mag.* Dec. 2, vol. vii. p. 414), that I need not enter into further details, though I am well aware that the subject is by no means exhausted.

For a like reason I may pass briefly over the remarkable erratics found in the Cambridge greensand (Sollas and Jukes-Browne, *Q. J. G. S.* vol. xxix. p. 11). They occasionally slightly exceed a cubic foot in volume, but are generally smaller. Among them are diverse sandstones and grits, probably Palæozoic, granite, gneiss, various schists, quartzites, and slates, besides greenstone, a very coarse gabbro or hypersthenite, and a compact feldstone. I think it highly probable that many of these erratics came from the north, in some cases almost certainly from Scotland, and were transported by ice, though I am not satisfied that any exhibit true glacial striæ. In the south of England a boulder of old quartzose rock, perhaps a piece of a coarse quartz-vein, crushed and re-cemented, has been found by Mr. J. S. Gardner in the gault, and in the chalk we have the well-known cases of the granitic rock and other boulders at Penley, near Croydon, and of coal (Wealden or Jurassic) in Kent (Godwin-Austen, *Q. J. G. S.* vol. xvi. p. 327). Mr. Godwin-Austen describes other instances of pebbles in chalk, and I have received two or three small specimens from Mr. W. Hill, from about the horizon of the Melbourne rock, which, however, have not yet thrown any light on the subject.

Eocene.—Previous writers have called attention to the fact that the sand of the Thanet, Oldhaven, and Bagshot beds is mainly composed of quartz. This is abundantly confirmed by my own observations. So far as I have seen, in all these the grains are not, as a rule, conspicuously rounded. It can hardly be doubted that older sandstones or granitoid rocks lying to the west have furnished the materials of the Bagshot series, which still has so wide an extension in that direction; their lithological similarity would lead us to look towards the same quarter for the materials of the more limited Oldhaven and Thanet beds. The well-rolled flint pebbles in the Oldhaven series, and in occasional layers in the Bagshot, suggest the proximity of a shore-line of Upper Cretaceous rocks.

I have had no opportunity of adding to what has been written on the lithology of the limited Pliocene deposits in England, and, as stated at the outset, have excluded from the scope of this address all beds of later date, which have been so ably discussed by Mr. Mackintosh, Dr. Crosskey, and many other geologists.

Principles of Interpretation

In attempting to interpret the facts which I have enumerated we must bear in mind the following principles:—

(1) Pebbles indicate the action either of waves of the sea,[1] or of strong currents, marine or fluviatile.

(2) The zone in the sea over which the manufacture of pebbles can be carried on is generally a very narrow one. It extends from the high-tide line to the depth usually of a few feet below low-water mark. It is estimated that as a rule there is no disturbance of shingle at a greater depth than twenty feet below the latter. It is therefore probable that a thick and very widely extended pebble bed is not the result of wave action.

(3) The movement of the deeper waters of the sea as a rule is so slight that only the very finest sediment can be affected by it. Now and then great currents like the Gulf Stream, or more locally "races," may have sufficient power to transfer pebbles and sand, but instances of this will be exceptional, and confined to rather shallow water. The larger coast currents, however, may transport mud to considerable distances, but in directions parallel with the main trend of the shores.

(4) Except where very large rivers discharge their water into the ocean, or in some special case of (3), sediment is deposited comparatively near the shores of continents. Even in the case of very large rivers only the finer sediment is carried far from land. The *Challenger* soundings have shown that 150 miles is about the maximum distance from land within which any important quantity of detrital materials is deposited.[2] As a rule (so far as I can ascertain), the coarser sediments are generally deposited within a few miles of the coast. Hence this is fringed by a zone of sediment, which, after passing a maximum thickness within a short distance from the shore, gradually thins away. I doubt whether this detrital fringe is often more than seventy or eighty miles wide; probably the coarser sands do not usually extend for so much as a quarter of this distance. The inertia of the mass of the ocean water quickly arrests the flow of even the mightiest river or reduces it to a mere superficial current. Hence the great ocean basins are regions where rock-building is carried on slowly and chiefly by organic agency. Their borders bear the burden, and the load taken off the continent is laid down on the bed of the adjacent sea.

(5) Thus rain and rivers are generally more important agents of denudation and transportation than the sea, because unless the land be rising or sinking the zone over which the latter can operate is limited both vertically and horizontally.

(6) The coarser materials of rock are capable of being transported by streams to considerable distances without serious diminution of volume. Prof. Daubrée has proved experimentally that a stream flowing at the rate of about two miles per hour would roll angular fragments of quartz or hard granite into perfectly smooth pebbles after a transit of 25 kilometres ($15\frac{5}{8}$ miles). During this process the fragments lost about four-tenths of their weight. Further transport reduced the volume of the pebbles very slowly. The loss afterwards varied from 1/1000 to 4/1000 per kilometre. To reduce a pebble of 2 inches diameter to 1 inch diameter—that is, to diminish its volume by seven-eighths—would require a journey of from about 219 to 875 kilometres (approximately from 137 to 548 miles). This approximation, rough as it is, becomes still less exact as the pebbles decrease in size; the rate of diminution in volume (*cæteris paribus*) bearing a relation to the area of the surface. Thus the smaller the pebble the further it will travel without material diminution of size. Sand grains are even rounded with extreme

[1] Prof. Rupert Jones has called attention to sand-worn pebbles in the Upper Tunbridge Wells sandstone of the Weald (*Geol. Mag.* Dec. 2, vol. v. p. 287).

[1] The waves of lakes also have some rounding effect, but this—except in the case of very large lakes, such as Lake Superior—is not important; and such cases are, of course, not of common occurrence.

[2] I except floating pumice, cosmic dust, &c., as comparatively unimportant.

slowness. According to the same author a quartz grain 1/50 inch in diameter requires to be transported by water action some 3000 miles before losing its angles. On this account the presence in a sandstone of numerous well-rounded grains is taken to indicate the action of wind, for, as is well known, blown sands are much more quickly rounded.[1]

(7) Thus deposits of gravel and coarse sand, of considerable vertical thickness and great extension, are more likely to indicate the immediate action of a river than of a marine current. If limited in extent they may have been formed at the embouchure of a river into a lake or sea. If, however, they can be traced for long distances, they are more probably in the main sub-aërial deposits from rivers.

The following examples may convey some idea of the kind of river which would be required to transport the more important deposits of grits and stones mentioned in the first section of this address:—

The old river-gravels of the Sierra Nevada are "in some places 300 or 400 feet thick and almost homogeneous from top to bottom," sometimes they even obtain a thickness of 600 feet. Mr. Whitney is of opinion that the fall in these old river channels was probably from 100 to 130 feet per mile. Apparently, however, we need not invoke so large a fall as this. The total fall of the Danube is 3600 feet, and its length 1750 miles. From Passau to Vienna the fall is 1 in 2200, from Vienna to Old Moldava 1 in 10,000. Yet the velocity of the current from Vienna to Basias (fifteen miles above Old Moldava) is "from two to three knots an hour," depending on the amount of water. This would suffice to transport pebbles of the average size of the English Bunter. Below the Iron Gates the fall is still less rapid, but sand is carried down for a very considerable distance. If then the rivers of the old continental land resembled the larger streams of Europe, they would suffice for the transport of the materials with which we have dealt, especially if aided by coast currents after the debris had reached the sea.

(8) If boulders occur in a matrix consisting of fine mud, or mainly of organic material, they must (unless they are volcanic bombs) have floated thither either attached to large seaweeds or entangled in the roots of trees, or supported by ice. If they are rather numerous and a foot or more in diameter, in a marine deposit, the last is the most probable mode of transport. A cubic yard of ice will more than suffice to float a cubic foot of average rock.

Conclusion

The facts already mentioned, regarded in the light of the above principles, justify, in my opinion, the following inferences as to the past physical geography of our country. At the commencement of the Cambrian period great masses of Archæan rock, granites, gneisses, and schists, must have existed, not only on the western side of Britain, but also over a considerable tract of land now covered by the sea. Detritus from this continent became an important constituent in the Cambrian rocks, and in many cases, as at St. David's, in Anglesey, Carnarvonshire, &c., the shore-line must have been very near at hand. With the Cambrian period commences a long continued subsidence, so that its basement beds at different places are very probably not all of quite the same age. The land surface was from the first irregular, and it is very probable that waves of the sea were fretting away some parts, while rain and river, heat and cold, were still sculpturing others. But among the materials of the ancient land were not only granitoid rocks, gneisses, and schists, but also newer strata more distinctly of clastic origin, memorials of past denudation—quartzites and grits, phyllites and slates, not to mention others—and these, by their intimate structure, sometimes indicate that great earth-movements must have already occurred.[2] In many localities, perhaps as a result of these disturbances, there occurred, towards the conclusion of the Archæan period, great volcanic outbursts—by which, no doubt, numerous cones were built up, and many of the materials of the so-called Pebidian group were supplied. It is, I think, at present hardly safe to attempt to trace the exact land boundaries of the Cambrian ocean, but the enormous masses of Archæan material which are entombed in the earlier Palæozoic strata of Wales and of North-West Scotland can, I think, only be explained by the proximity of a great continental land—an extension of the present Scandinavian peninsula—which not improbably had a general slope towards the south-east, the main watershed of which may have lain some distance to the west of the Outer Hebrides.[1] But even over the more central parts of Britain there cannot have been deep or open ocean. We are constantly coming upon the traces of pre-Cambrian and early Cambrian land; some of our Mid-England Archæan masses, like the Malverns, appear to have risen above the water, and to have undergone denudation after the great earth-movements which ushered in the Silurian period. Prior to this, after a time of repose in the Cambrian, at more than one epoch, and in more than one place, there were great volcanic outbursts, which appear to have studded the sea with volcanic islands, and to have added to the heterogeneous materials from which the sediments were now formed. It is evident that in Silurian times the coast-line had extended southward and eastward. The coarse deposits of this age, in Wales, the Lake district, and Southern Scotland, compared with the finer mudstones and limestones of the Welsh border and of England, seem fully to bear out this assumption, which is in accordance with a well-known law of mountain-making. The Old Red Sandstone of Scotland and of Wales indicates a yet further continental extension towards the south east. A great epoch of mountain-making in the Scotch highlands, which had perhaps been going on at intervals from the beginning to the end of the Silurian period, had now come to an end; the southern uplands had risen up, like a Jura to the Alps. But probably their elevation did not terminate the earth-movements, for the post-Silurian cleavage of the Lake district, and the absence of Old Red Sandstone both here and in Central England indicate that the Palæozoic land mass continued to extend on its south-eastern flank. The Devonian period introduces us in the greater part of Great Britain to an epoch of limited and exceptional deposits, and of widely prevalent terrestrial conditions. It seems almost certain that the Old Red Sandstones of Scotland and Wales are of fresh-water origin—the deltas of rivers, formed either in lakes or possibly in part as sub-aërial deposits. Streams of considerable volume and of some strength are indicated by the materials. In one case, the Old Red Sandstone of North-East Scotland, we may perhaps discern in the Great Glen some indication of the old river course. It is easy to ascertain the source of the materials of the Scottish Old Red Sandstones. They are as obviously the detritus of the Highland mountains—then probably a far grander and loftier chain—as the nagelflue and the molasse of Switzerland are of the Alps.

At this time marine conditions prevailed in the south of England. The sea appears to have deepened towards the south, but I suspect that a region of crystalline rock still existed at no great distance in that direction and in the west. Probably the Brito-Scandinavian peninsula curved round to the east so as to include some part of Brittany.[2] Another great epoch of subsidence now commenced, commemorated by the formation of the Carboniferous limestone. At this I need hardly glance, as it has been so fully discussed by Prof. Hull and other writers. The land sank both in the north and in the south of England. There was deep sea over Derbyshire and Southern Wales, but the ground beneath our feet probably remained above water, forming either a continental promontory or a large island.

There were other well-known interruptions to the sea, which also overflowed a considerable part of Ireland and districts far to the east of England. The Scotch highlands, however, probably remained above water, for, as is well known, the Carboniferous limestone of Central Scotland overlies a fresh-water formation, and is itself not wholly marine, since it contains coal, and like conditions prevailed in Northumberland.

Gradually, however, the sea shallowed, and terrestrial conditions returned. In the later part of the Carboniferous series we have clear indications of two, or perhaps three, important currents, almost certainly those of rivers, bringing materials, in the southern district from the west; in the northern, from the north-west and probably the north-east. These materials may have been in part derived from older Palæozoic rocks, but the facts when fairly considered seem to indicate that there was also an extensive denudation of crystalline and not improbably Archæan rocks, unless we suppose that great areas of eruptive Palæozoic granite have now disappeared beneath the waters. At any rate, we may perhaps regard the open water between Ireland

[1] See on the subject of this paragraph Daubrée, "Géol. Expériment.," vol. i. sec. 2, ch. i., and J. A. Phillips, *Q. J. G. S.*, vol. xxxvii. p. 21, &c.

[2] It is evident, for instance, that the north-west strike, and other effects of folding, had been produced in the Hebridean series of North-West Scotland before the Torridon sandstone was deposited.

[1] Possibly the comparatively rapid deepening of the Atlantic beyond the 100-fathom line may have some relation to the western outline of this primæval Atlantis.

[2] Compare, as an illustration, the curving round of the Alpine chain on the western side of Italy.

and Scotland on the one hand, and to the east of the latter country on the other, as significant of a denudation earlier than that of the sea which has in later times divided the British Isles. Another epoch of earth-movements closed—as was to be expected—the Carboniferous subsidence and deposition. We trace one line of flexures and of intense compression along a broad zone, including the south of England, from Germany to Ireland; another less intense over the northern part of our country; the axes of the former flexure striking a little north of west, of the latter about west-south-west. The one appears to me to indicate a thrust from a great mass of hard, more or less crystalline rock in the south, which probably led to the formation of a mountain-chain extending from North-Central Europe over the Channel to the southern margin of England. The latter may be explained by the presence of the above-named north-western continent.

In the Permian time terrestrial conditions probably prevailed over a large part of Britain. It is extremely difficult to ascertain the exact circumstances under which the Permian beds of Central England were deposited, but I should think they imply a return to physical conditions not unlike those of the Old Red Sandstone, though perhaps the marine fossils which have been found in Warwickshire may indicate that the water there had some imperfect connection with the sea. I must not discuss the vexed question of the age of the Pennine Chain, but must content myself with expressing my opinion that, at most, it can only, as yet, have very partially interrupted the continuity of the water in Northern England. The beds there appear to indicate a supply of materials from the north and north-west, as if the old rivers had not been wholly diverted by the great earth-movements which closed the Carboniferous period. Sir A. Ramsay's view, that the water in which the dolomitic limestone was deposited was more or less cut off from the open sea, seems to me by no means improbable; in any case, it is a rather exceptional formation, and over the greater part of Britain, probably, land sculpture continued, and deposition was on the whole local.

With the Trias a new era commences; physical features had been now produced, which in all probability endured through a considerable part of Mesozoic times. The facts which I have laid before you, regarded in the light of the general principles indicated above, compel us to look away from the immediate vicinity for the bulk of the materials, coarse and fine, of which the northern Trias is composed, though neighbouring hills may have furnished occasional contributions, especially to the earlier deposits. The analogy of the Old Red Sandstone, the Calciferous Sandstone of Scotland, and the Nagelflue and Molasse of Switzerland, together with other peculiarities too well known to need repetition, make it in the highest degree probable that the Bunter beds were not deposited in the ocean.[1] Hence they must be either deltas formed in an inland sea or in a lake, or true fluviatile deposits. Neither lake nor inland sea appears likely to have been sufficiently large to admit of waves or currents capable of either rounding the pebbles or transporting the materials. We are therefore compelled to fall back upon the action of rivers. The sandy beds of the Bunter indicate a stream flowing from one-third to half a mile an hour, the pebbles one from two to three miles; that is to say, the Upper and Lower Bunter sandstones would require the former rate of movement, the Pebble Beds the latter. Now, we must remember that, in the West-Central district, the Lower Trias consists of three wedge-like masses, about a hundred miles in length, of which the coarser is probably the more extensive. The comparative uniformity of the deposits in each case indicates a uniformity of flow, and suggests either a large and broad stream, not liable to much variation, or one which, when flooded, quickly made a channel of its valley, and deposited mainly at such season. I have the greatest difficulty in understanding how a current of the requisite velocity could be maintained by the water of a river or rivers flowing into a lake or an inland sea, or in explaining the tripartite arrangement of the beds on the hypothesis that a basin was gradually filled up from the northward by a stream which, like the Rhone at the upper end of the Lake of Geneva, gradually advanced its delta by flowing over the materials which it had previously deposited in the basin. Hence I believe that we must regard the Bunter beds as subaerial deltas, analogous to the conglomerates in the Siwalik deposits of India,[2] and to the sandstone and nagelflue on the outer zone of the Alps, deposits in all respects very similar to the English Bunter. We may suppose, then, that rivers emerging on each side of the Pennine Chain from a mountain land first formed the Lower Bunter sandstones, then, owing to increasing upheaval in the mountain district, and corresponding depression in the lowlands, flowed more swiftly so as to cover this deposit with the Pebble Bed, and lastly, as its former conditions returned, laid upon this the Upper sandstones. I have spoken, for the sake of clearness, as if these were perfectly distinct formations, but it would by no means follow that some part of the finer beds to the south-east might not be contemporaneous with a portion of the coarser beds to the north-west, as the velocity first increased, and then diminished. As I have already said, the materials of the pebbles and of the sand make it impossible to refer the main constituents to local sources. Many of the rocks do not exist in the Midland; there is no reason to suppose that at that time there were in this region masses of land of sufficient area and height to feed important rivers.[1] From currents of any other kind we are precluded, so that I believe we may safely turn our eyes northward and look for the ultimate source of the Triassic sandstones and conglomerates among the older rocks of the Scotch highlands, and their extension to east and to west, though very probably the materials may have been more directly supplied from Old Red Sandstone and early Carboniferous strata, in remnants of which identical fragments may still be seen. In like way we may regard the Trias of the south of England as the detritus of at least one great river, which flowed from the west or south-west. The materials of the Keuper came from the same directions in each case, but here, I think, we have indications of deposition in an inland sea. Breccias formed on its coasts, and sands were at first deposited in it; but presently the area of water increased, and the coarser materials must have been arrested in the uplands, while the fine sediment which forms the marls may have been carried out into the salt lake and slowly settled down in its calm waters.[2] Its shores may have been hardly more favourable to a vigorous development of life than were its salt-saturated waters; during this period and the preceding Bunter the lowland border of the mountains, like some of the northern districts of India, may have been arid and barren regions of shifting sands.

The Trias of Northern Scotland very probably indicates a repetition on a more restricted scale of the physical conditions of the Old Red Sandstone, but after this we observe signs of an encroachment of the Atlantic on the above-named old area of continental land.

The Jurassic series is represented in Northern Scotland on both the western and eastern coasts by marine or estuarine beds. This probably indicates important modifications in the river channels, subsidence on the west altering the slopes, reducing the length, and cutting away some of the feeding-ground. Traces may still be discerned in England of the two northern rivers, but that which in Triassic times was the larger contributor, appears in Jurassic to have been gradually enfeebled; the other one and the south-western stream seem to have still flowed with some strength. Sands, however, now become comparatively local. Probably the coarser materials, as a rule, did not reach the sea. This appears at all times to have been comparatively shallow and inclosed by land on every side but the south-east. The recent discovery of Oxford Clay beneath the Cretaceous beds at Chatham suggests that a narrow strait running in a northerly direction may have insulated the Palæozoic rocks

[1] Compare also the Bunter and Keuper in the region traversed by the German Rhine.

[2] The analogy of the Indian conglomerates was suggested to me by Dr. Blanford. See *Geol. Mag.* Dec. 2, vol. x. p. 514.

[1] It may be useful to give a rough idea of the quantity of rock which must have been denuded in order to obtain materials for the Bunter beds. Suppose, for purposes of calculation, we consider the Bunter beds, which cover the district from the Cheshire coast to the Midland counties, as forming the section of a cone contained by two planes drawn through the axis so as to include an angle of 30°. If h be the height of this axis, and r the radius of the base, the volume of this figure is $\frac{\pi r^2 h}{36}$. Take, for purposes of rough calculation, $h = \frac{1}{4}$ mile, $r = 80$ miles, $\pi = 3$; the volume is about 133 cubic miles. Conceive this piled up to form a long mound, in section an isosceles triangle 1 mile high, with a base of 4 miles. The length would be over 65 miles. Thus the materials buried in the Bunter beds of the above-named district represent a chain of hills unfurrowed by valleys 5000 feet high, 4 miles wide, and 65 miles long. Suppose the Pebble Bed, a like slice of a cone, axis one-tenth of a mile, base 70 miles; the volume is more than 40 cubic miles. Suppose the quartz and quartzite pebbles one-tenth of its volume; these represent a mass of 4 cubic miles, or a line of hills like the above 1000 feet high, 2 miles wide, and 20 long.

[2] The lake may have gradually become salt, or possibly the Muschelkalk sea may have for a short space invaded Britain, and then have been insulated like the Caspian.

beneath the London district. The clays of the Lias, Oxfordian, and Kimmeridgian probably indicate a direct discharge of sediment into the sea,[1] the limestones, depression sufficing to convert valleys into fjords, in the upper parts of which sediment was deposited so that the waters of the sea were clear. The deposits of the Purbeck and Weald indicate that the western river still drained an extensive area, and a gradual rise of land in later Jurassic times, especially towards the south, appears to have advanced the river delta eastwards, and to have limited the area of the Jurassic sea on the north.

Towards the end of the Neocomian, owing to a widespread subsidence, the sea once more returned to South-Eastern England, and a communication appears to have been opened between it and the Speeton basin. This comparatively narrow strait was a region of considerable denudation and of strong and shifting coast currents.[2] The Cretaceous subsidence at first brought back physical conditions not very different from those prevalent in Oxfordian and Kimmeridgian times, but later on a very considerable depression must have so far submerged the northern continental land as either to break up the parts adjacent to Britain into groups of islands, or at least to flood the valleys so completely as to prevent any discharge of sediment into the sea. The erratics of the Cambridge Greensand suggest that a free communication into the northern ocean was established, anterior to the formation of the Chalk marl, through some part of the present interval between Scotland and Scandinavia, so as to set up a coast current with a southerly drift of shore ice near the eastern part of England; to this also may be due the erosion of the Cambridgeshire Gault.

The larger part of Britain was dry land during the Eocene, though the sea after retreating appears to have again encroached over the southern and eastern districts of England. The sands may indicate that the western river again resumed its course;[3] the extension of the London Clay up our eastern coast suggests that the northern river still flowed. But with the important disturbances which closed the Eocene and ushered in the continental conditions of the Miocene—new flexures along the old east and west lines—the earlier physical features appear to have been finally obliterated, and the sculpture of the English lowlands began. The tale of the volcanic outbursts of Western Scotland has been so well told by my friend and predecessor Prof. Judd that I need do no more than recall it to your minds. The Pliocene deposits of Eastern England indicate a new encroachment of the Franco-Belgian Tertiary sea.

Thus ends my sketch, too lengthy, I fear, for your patience, yet too brief to allow of a complete treatment of the subject. It may, however, suffice to indicate that in geology the "task of the least" is by no means despicable, and that great results may be hoped from apparently small means; that in this search for "Atlantis through the micro-cope" we may find it very near at hand, and may discover analogies, as has been indicated in our President's address, between the two borders of the ocean which severs Europe from America. An enlarged study of the materials of our Palæozoic and later detrital rocks may indicate that from very early times there has been a recurrence of similar physical conditions, and that in geology also a recurrence of effects indicates a recurrence of the same causes. The facts which I have brought before you have justified, I trust, my opening remarks as to the rich harvest which yet awaits investigations into the structure of the fragmental rocks. To resume the simile then used, I see the land of promise, stretching far away from beneath my feet, till it seems to melt into the dim and as yet unknown distance. Not speedily will its riches be exhausted. Our hands will long have vanished, our voices will long have been still, before the work of discovery is ended, and men have reached the shore of that circumfluent ocean which, at least in this life, limits their finite powers.

[1] The considerable distance to which the clays extend in a southerly direction may possibly indicate that, to the east of Scotland, a communication had now been opened with the northern ocean, which had set up a current along the coast east of the Pennine Chain.

[2] As the Speeton beds continue to be clays, one would infer a drift from the south, but a current to the opposite direction would be more probable, and it is the opinion of Dr. Sorby that this was the case. His papers "On the Direction of the Currents indicated by the Coarse Sediments in our British Rocks" are most valuable (*Yorks. Geol. Pol. Soc.* v. 220, &c.).

[3] The occasional beds of flint pebbles indicate a neighbouring shore line of Cretaceous rocks rather than the denudation of beds of Cretaceous age, which had been deposited on parts of the western land during the period of depression.

SECTION D

BIOLOGY

Opening Address by William Carruthers, Pres.L.S., F.R.S., F.G.S., President of the Section

In detaining you a few minutes from the proper work of the Section, I propose to ask your attention to what is known of the past history of the species of plants which still form a portion of the existing flora. The relation of our existing vegetation to preceding floras is beyond the scope of our present inquiry: it has been frequently made the subject of exposition, but to handle it requires a more lively imagination than I can lay claim to, or, perhaps, than it is desirable to employ in any strictly scientific investigation.

The literature of science is of little, if any, value in tracing the history of species, and in determining the modification or the persistency of characters which may be essential or accidental to them. If help could be obtained from this quarter, botanical inquiry would be specially favoured, for the literature of botany is earlier, and its terms have all along been more exact than in any of her sister sciences. But even the latest descriptions, incorporating as they do the most advanced observations of science, and expressed in the most exact terminology, fail to supply the data on which a minute comparison of plants can be instituted. Any attempt to compare the descriptions of Linnæus and the earlier systematists who, under his influence, introduced greater precision into their language, with the standard authors of our own day, would be of no value. The short, vague, and insufficient descriptions of the still earlier botanists cannot even be taken into consideration.

Greater precision might be expected from the illustrations that have been in use in botanical literature from the earliest times; but these really supply no better help in the minute study of species than the descriptions which they are intended to aid. The earliest illustrations are extremely rude: many of them are misplaced; some are made to do duty for several species, and not a few are purely fictitious. The careful and minutely exact illustrations which are to be found in many modern systematic works are too recent to supply materials for detecting any changes that may have taken place in the elements of a flora.

But the means of comparison which we look for in vain in the published literature of science may be found in the collections of dried plants which botanists have formed for several generations. The local herbaria of our own day represent not only the different species found in a country, but the various forms which occur, together with their distribution. They must supply the most certain materials for the minute comparison at any future epoch of the then existing vegetation with that of our own day.

The preservation of dried plants as a help in the study of systematic botany was first employed in the middle of the sixteenth century. The earliest herbarium of which we have any record is that of John Falconer, an Englishman who travelled in Italy between 1540 and 1547, and who brought with him to England a collection of dried plants fastened in a book. This was seen by William Turner, our first British botanist, who refers to it in his "Herbal," published in 1551. Turner may have been already acquainted with this method of preserving plants, for in his enforced absence from England he studied at Bologna under Luca Ghini, the first Professor of Botany in Europe, who, there is reason to believe, originated the practice of making herbaria. Ghini's pupils, Aldrovandus and Cæsalpinus, formed extensive collections. Caspar Bauhin, whose "Prodromus" was the first attempt to digest the literature of botany, left a considerable herbarium, still preserved at Basle. No collection of English plants is known to exist older than the middle of the seventeenth century; a volume containing some British and many exotic plants collected in the year 1647 was some years ago acquired by the British Museum. Towards the end of that century great activity was manifested in the collection of plants, not only in our own country, but in every district of the globe visited by travellers. The labours of Ray and Sloane, of Petiver and Plukenet are manifest not only in the works which they published, but in the collections that they made, which were purchased by the country in 1759 when the museum of Sir Hans Sloane became the nucleus of the now extensive collections of the British Museum. The most important of these collections in regard to British plants is the herbarium of Adam Buddle, collected nearly 200 years ago, and containing an extensive series, which formed the basis of a

British flora, that unhappily for science was never published, though it still exists in manuscript. Other collections of British plants of the same age, but less complete, supplement those of Buddle: these various materials are in such a state of preservation as to permit of the most careful comparison with living plants, and they show that the two centuries which have elapsed since their collection have not modified in any particular the species contained in them. The early collectors contemplated merely the preservation of a single specimen of each species; consequently the data for an exhaustive comparison of the indigenous flora of Britain at the beginning of last century with that of the present are very imperfect as compared with those which we shall hand down to our successors for their use.

The collections made in other regions of the world in the seventeenth century, and included in the extensive herbarium of Sir Hans Sloane, are frequently being examined side by side with plants of our own day, but they do not show any peculiarities that distinguish them from recent collections. If any changes are taking place in plants, it is certain that the 300 years during which their dried remains have been preserved in herbaria have been too short to exhibit them.

Beyond the time of those early herbaria the materials which we owe in any way to the intervention of man have been preserved without any regard to their scientific interest. They consist mainly of materials used in building or for sepulture. The woods employed in mediæval buildings present no peculiarities by which they can be distinguished from existing woods; neither do the woods met with in Roman and British villages and burying-places. From a large series collected by General Pitt-Rivers in extensive explorations carried on by him on the site of a village which had been occupied by the British before and after the appearance of the Romans, we find that the woods chiefly used by them were oak, birch, hazel, and willow, and at the latter period of occupation of the village the wood of the Spanish chestnut (*Castanea vulgaris*, Lamk.) was so extensively employed that it must have been introduced and grown in the district. The gravel beds in the north of London, explored by Mr. W. G. Smith for the palæolithic implements in them, contained also fragments of willow and birch, and the rhizomes of *Osmunda regalis*, L.

The most important materials, however, for the comparison of former vegetation of a known age with that of our own day have been supplied by the specimens which have been obtained from the tombs of the ancient Egyptians. Until recently these consisted mainly of fruits and seeds. These were all more or less carbonised, because the former rifling of the tombs had exposed them to the air. Ehrenberg, who accompanied Von Minutoli in his Egyptian expedition, determined the seeds which he had collected; but as he himself doubted the antiquity of some of the materials on which he reported, the scientific value of his enumeration is destroyed. Passalacqua in 1823 made considerable collections from tombs at Thebes, and these were carefully examined and described by the distinguished botanist Kunth. He pointed out, in a paper published sixty years ago, that these ancient seeds possessed the minute and apparently accidental peculiarities of their existing representatives. Unger, who visited Egypt, published in several papers identifications of the plant remains from the tombs; and one of the latest labours of Alexander Braun was an examination of the vegetable remains in the Egyptian Museum at Berlin, which was published, afer his death, from his manuscript, under the careful editorship of Ascherson and Magnus. In this, twenty-four species were determined, some from imperfect materials, and necessarily with some hesitation as to the accuracy of their determination.

The recent exploration of unopened tombs belonging to an early period in the history of the Egyptian people has permitted the examination of the plants in a condition which could not have been anticipated. And happily, the examination of these materials has been made by a botanist who is thoroughly acquainted with the existing flora of Egypt, for Dr. Schweinfurth has for a quarter of a century been exploring the plants of the Nile valley. The plant-remains were included within the mummy-wrappings, and, being thus hermetically sealed, have been preserved with scarcely any change. By placing the plants in warm water, Dr. Schweinfurth has succeeded in preparing a series of specimens gathered 4000 years ago, which are as satisfactory for the purposes of science as any collected at the present day. These specimens consequently supply means for the closest examination and comparison with their living representatives. The colours of the flowers are still present, even the most evanescent, such as the violet of the larkspur and knapweed, and the scarlet of the poppy; the chlorophyll remains in the leaves, and the sugar in the pulp of the raisins. Dr. Schweinfurth has determined no less than fifty-nine species, some of which are represented by the fruits employed as offerings to the dead, others by the flowers and leaves made into garlands, and the remainder by branches on which the body was placed, and which were inclosed within the wrappings.

[The following is a list of the species of ancient Egyptian plants determined by Dr. Schweinfurth; I am indebted to Dr. Schweinfurth for some species in this list, the discovery of which he has not yet published:—*Delphinium orientale*, Gay; *Cocculus Leaba*, DC.; *Nymphæa cærulea*, Sav.; *Nymphæa Lotus*, Hook.; *Papaver Rhœas*, L.; *Sinapis arvensis*, L., var. *Allionii*, Jacq.; *Mærua uniflora*, Vahl.; *Oncoba spinosa*, Forsk.; *Tamarix nilotica*, Ehrb.; *Alcea ficifolia*, L.; *Linum humile*, Mill.; *Balanites ægyptiaca*, Del.; *Vitis vinifera*, L.; *Moringa aptera*, Gærtn.; *Medicago denticulata*, Willd.; *Sesbania ægyptiaca*, Pers.; *Faba vulgaris*, Mœnch; *Lens esculenta*, Mœnch; *Lathyrus sativus*, L.; *Cajanus indicus*, L.; *Acacia nilotica*, Del.; *Lawsonia inermis*, Lamk.; *Punica Granatum*, L.; *Epilobium hirsutum*, L.; *Lagenaria vulgaris*, Ser.; *Citrullus vulgaris*, Schrad., var. *colocynthoides*, Schweinf.; *Apium graveolens*, L.; *Coriandrum sativum*, L.; *Cenuana pratensis*, Forsk.; *Sphæranthus suaveolens*, DC.; *Chrysanthemum coronarium*, L.; *Centaurea depressa*, M. Bieb.; *Carthamus tinctorius*, L.; *Picris coronopifolia*, Asch.; *Mimusops Schimperi*, Hochst.; *Jasminum Sambac*, L.; *Olea europæa*, L.; *Mentha piperita*, L.; *Rumex dentatus*, L.; *Ficus Sycomorus*, L.; *Ficus Carica*, L.; *Salix Safsaf*, Forsk.; *Juniperus phœnicea*, L.; *Pinus Pinea*, L.; *Allium sativum*, L.; *Allium Cepa*, L.; *Phœnix dactylifera*, L.; *Calamus fasciculatus*, Roxb.; *Hyphæne thebaica*, Mart.; *Medemia Argun*, P. G. von Würtemb,; *Cyperus Papyrus*, L.; *Cyperus esculentus*, L.; *Andropogon laniger*, Desf.; *Leptochloa bipinnata*, Retz.; *Triticum vulgare*, L.; *Hordeum vulgare*, L.; *Parmelia furfuracea*, Ach.; *Usnea plicata*, Hoffm.]

The votive offerings consist of the fruits, seeds, or stems, of twenty-nine species of plants. Three palm fruits are common: the *Medemia Argun*, Würt., of the Nubian Desert, and the *Hyphæne thebaica*, Mart., of Upper Egypt, agreeing exactly with the fruits of these plants in our own day; also dates of different forms resembling exactly the varieties of dried dates found now in the markets of Egypt. Two figs are met with, *Ficus Carica*, L., and *Ficus Sycomorus*, L., the latter exhibiting the incisions still employed by the inhabitants for the destruction of the Neuropterous insects which feed on them. The sycamore was one of the sacred trees of Egypt, and the branches used for the bier of a mummy found at Abd-el-Qurna, of the twentieth dynasty (a thousand years before the Christian era), were moistened and laid out by Dr. Schweinfurth, equalling, he says, the best specimen of this plant in our herbaria, and consequently permitting the most exact comparison with living sycamores, from which they differ in no respect. The fruit of the vine is common, and presents, besides some forms familiar to the modern grower, others which have been lost to cultivation. The leaves which have been obtained entire exactly agree in form with those cultivated at the present day, but the under surface is clothed with white hairs, a peculiarity Dr. Schweinfurth has not observed in any Egyptian vines of our time. A very large quantity of linseed was found in a tomb at Thebes of the twentieth dynasty, now 3000 years old, and a smaller quantity in a vase in another tomb of the twelfth dynasty, that is, 1000 years older. This belongs certainly to *Linum humile*, Mill., the species still cultivated in Egypt, from which the capsules do not differ in any respect. Braun had already determined this species preserved thus in the tombs, though he was not aware of its continued cultivation in Egypt. The berries of *Juniperus phœnicea*, L., are found in a perfect state of preservation, and present a somewhat larger average size than those obtained from this juniper at the present day. Grains of barley and wheat are of frequent occurrence in the tombs; M. Mariette has found barley in a grave at Sakhara of the fifth dynasty, 5400 years old.

The impurities found with the seeds of these cultivated plants show that the weeds which trouble the tillers of the soil at the present day in Egypt were equally the pests of their ancestors in those early ages. The barley-fields were infested with the same spiny medick (*Medicago denticulata*, Willd.) which is still found in the grain crops of Egypt. The presence of the pods

of *Sinapis arvensis*, L., among the flax seed testifies to the presence of this weed in the flax crops of the days of Pharaoh, as of our own time. There is not a single field of flax in Egypt where this charlock does not abound, and often in such quantity that its yellow flowers, just before the flax comes into bloom, present the appearance of a crop of mustard. The charlock is *Sinapis arvensis*, L., var. *Allionii*, Jacq., and is distinguished from the ordinary form by its globular and inflated silicules, which are as characteristically present in the ancient specimens from the tombs as in the living plants. *Rumex dentatus*, L., the dock of the Egyptian fields of to-day, has been found in graves of the Greek period at Dra-Abu-Negga.

It is difficult without the actual inspection of the specimens of plants employed as garlands, which have been prepared by Dr. Schweinfurth, to realise the wonderful condition of preservation in which they are. The colour of the petals of *Papaver Rhœas*, L., and the occasional presence of the dark patch at their bases present the same peculiarities as are still found in this species growing in Egyptian fields. The petals of the larkspur (*Delphinium orientale*, Gay) not only retain their reddish-violet colour, but present the peculiar markings which are still found in the living plant. A garland composed of wild celery (*Apium graveolens*, L.) and small flowers of the blue lotus (*Nymphæa cærulea*, Sav.), fastened together by fibres of papyrus, was found on a mummy of the twentieth dynasty, about three thousand years old. The leaves, flowers, and fruits of the wild celery have been examined with the greatest care by Dr. Schweinfurth, who has demonstrated in the clearest manner their absolute identity with the indigenous form of this species now abundant in moist places in Egypt. The same may be said of the other plants used for garlands, including two species of lichens.

It appears to have been a practice to lay out the dead bodies on a bier of fresh branches, and these were inclosed within the linen wrappings which enveloped the mummy. In this way there have been preserved branches of considerable size of *Ficus Sycomorus*, L., *Olea europæa*, L., *Mimusops Schimperi*, H., and *Tamarix nilotica*, Ehrb. The Mimusops is of frequent occurrence in the mural decorations of the ancient temples; its fruit had been detected amongst the offerings to the dead, and detached leaves had been found made up into garlands, but the discovery of branches with their leaves still attached, and in one case with the fruit adhering, has established that this plant is the Abyssinian species to which Schimper's name has been given, and which is characterised by the long and slender petiole of the leaf.

In none of the species, except the vine to which I have referred, which Dr. Schweinfurth has discovered, and of which he has made a careful study, has he been able to detect any peculiarities in the living plants which are absent in those obtained from the tombs.

Before passing from these Egyptian plants I would draw attention to the quality of the cereals. They are good specimens of the cereals still cultivated. This observation is true also of the cultivated grains which I have examined, belonging to prehistoric times. The wheat found in the purely British portion of the ancient village explored by General Pitt-Rivers is equal to the average of wheat cultivated at the present day. This is the more remarkable, because the two samples from the later Romano-British period obtained by General Pitt-Rivers are very much smaller, though they are not unlike the small hard grains of wheat still cultivated on thin chalk soils. The wheat from lake-dwellings in Switzerland, for which I am indebted to Mr. J. T. Lee, F.G.S., are fair samples. My colleague, Mr. W. Fawcett, has recently brought me, from America, grains of maize from the prehistoric mounds in the valley of the Mississippi, and from the tombs of the Incas of Peru, which represent also fair samples of this great food substance of the New World. The early peoples of both worlds had then under cultivation productive varieties of these important food-plants, and it is remarkable that in our own country, with all the appliances of scientific cultivation and intelligent farming, we have not been able to appreciably surpass the grains which were harvested by our rude ancestors of 2000 years ago.

In taking a further step into the past, and tracing the remains of existing species of plants preserved in the strata of the earth's crust, we must necessarily leave behind all certain chronology. Without an intelligent observer and recorder there can be no definite determination of time. We can only speculate as to the period required for effecting the changes represented by the various deposits.

The peat-bogs are composed entirely of plant-remains belonging to the floras existing in the regions where they occur. They are mainly surface-accumulations still being formed and going back to an unknown antiquity. They are subsequent to the last changes in the surface of the country, and represent the physical conditions still prevailing.

The period of great cold during which Arctic ice extended far into temperate regions was not favourable to vegetable life. But in some localities we have stratified clays with plant-remains later than the Glacial epoch, yet indicating that the great cold had not then entirely disappeared. In the lacustrine beds at Holderness is found a small birch (*Betula nana*, L.), now limited in Great Britain to some of the mountains of Scotland, but found in the Arctic regions of the Old and New World and in Alpine districts in Europe, and with it *Prunus Padus*, L., *Quercus Robur*, L., *Corylus Avellana*, L., *Alnus glutinosa*, L., and *Pinus sylvestris*, L. In the white clay beds at Bovey Tracey of the same age there occur the leaves of *Arctostaphylos Uva-Ursi*, L., three species of willow, viz. *Salix cinerea*, L., *S. myrtilloides*, L., and *S. polaris*, Wahl., and in addition to our alpine *Betula nana*, L., the more familiar *B. alba*, L. In beds of the same age in Sweden, Nathorst has found the leaves of *Dryas octopetala*, L., and *Salix herbacea*, L., this being associated with *S. polaris*, Wahl. Two of these plants have been lost to our flora from the change of climate that has taken place, viz. *Salix myrtilloides*, L., and *S. polaris*, Wahl.; and *Betula nana*, L., has retreated to the mountains of Scotland. Three others (*Dryas octopetala*, L., *Arctostaphylos Uva-Ursi*, L., and *Salix herbacea*, L.), have withdrawn to the mountains of Northern England, Wales, and Scotland, while the remainder are still found scattered over the country. Notwithstanding the diverse physical conditions to which these plants have been subjected, the remains preserved in these beds present no characters by which they can be distinguished from the living representatives of the species.

We meet with no further materials for careful comparison with existing species until we get beyond the great period of intense cold which immediately preceded the present order of things. The Glacial epoch includes four periods during which the cold was intense, separated by intervals of somewhat higher temperature, which are represented by the intervening sedimentary deposits. During these alterations of temperature, extensive changes in the configuration of the land were taking place. The first great upheaval occurred in the early Glacial period, and was followed by a considerable subsidence. A second upheaval took place late in the Glacial epoch. Various estimates have been formed of the time required for this succession of climatic conditions and earth-movements. The moderate computation of Ramsay and Lyell gives to the boulder-clay of the first Glacial period an age of 250,000 years, estimating the time of the first upheaval as 200,000 years ago, while the subsidence took place 50,000 years later, and the second upheaval 92,000 years ago.

The sedimentary deposits later than the Pliocene strata, but older than the Glacial drift, indicate an increasing severity in the climate, which reached its height in the first Glacial period.

At Cromer, on the Norfolk coast, the newest of these deposits has supplied the remains of *Salix polaris*, Wahl., *S. cinerea*, L., and *Hypnum turgescens*, Schimp. This small group of plants is of great interest in connection with the history of existing species; their remains are preserved in such a manner as to permit the closest comparison with living plants. Such an examination shows that they differ from each other in no particular. In the post-Glacial deposits in Sweden, *Salix herbacea*, L., is associated with *S. polaris*, Wahl., as I have already stated. These two willows are very closely related, having indeed been treated as the same species until Wahlenberg pointed out the characters which separated them when he established *Salix polaris* as a distinct species in 1812. One of the most obvious of the specific distinctions is the form and venation of the leaf, a character which is, however, easily overlooked, but when once detected is found to be so constant that it enables one to distinguish without hesitation the one species from the other. The leaves of the two willows in the Swedish bed present all the peculiarities which they possess at the present day, and the venation and form of the leaves of *S. polaris*, Wahl., from the pre-Glacial beds of Cromer, present no approach towards the peculiarities of its ally *S. herbacea*, L., but exhibit them exactly as they appear in the living plant. This is the more noteworthy as the vegetative organs supply, as a rule, the least stable of the

characters employed in the diagnosis of species. The single moss (*Hypnum turgescens*, Schimp.) is no longer included in the British flora, but is still found as an Arctic and Alpine species in Europe, and the pre-Glacial specimens of this cellular plant differ in no respect from their living representatives.

The older beds containing the remains of existing species, which are found also at Cromer, have recently been explored with unwearied diligence and great success by Mr. Clement Reid, F.G.S., an officer of the Geological Survey of England. To him I am indebted for the opportunity of examining the specimens which he has found, and I have been able to assist him in some of his determinations, and to accept all of them. His collections contain sixty-one species of plants belonging to forty-six different genera, and of these forty-seven species have been identified. Slabs of clay-ironstone from the beach at Happisburgh contain leaves of beech, elm, oak, and willow. The materials, however, which have enabled Mr. Reid to record so large a number of species are the fruits or seeds which occur chiefly in mud or clay, or in the peat of the forest bed itself. The species consist mainly of water or marsh plants, and represent a somewhat colder temperature than we have in our own day, belonging as they do to the Arctic facies of our existing flora.

Only one species (*Trapa natans*, L.), has disappeared from our islands; its fruits, which Mr. Reid found abundantly in one locality, agree with those of the plants found until recently in the lakes of Sweden. Four species (*Prunus spinosa*, L., *Œnanthe Lachenalii*, Gmel., *Potamogeton heterophyllus*, Schreb., and *Pinus Abies*, L.) are found at present only in Europe, and a fifth (*Potamogeton trichoides*, Cham.) extends also to North America; two species (*Peucedanum palustre*, Mœnch, and *Pinus sylvestris*, L.) are found also in Siberia, whilst six more (*Sanguisorba officinalis*, L., *Rubus fruticosus*, L., *Cornus sanguinea*, L., *Euphorbia amygdaloides*, L., *Quercus Robur*, L., and *Potamogeton crispus*, L.) extend into Western Asia, and two (*Fagus sylvatica*, L., and *Alnus glutinosa*, L.) are included in the Japanese flora. Seven species, while found with the others, enter also into the Mediterranean flora, extending to North Africa: these are *Thalictrum minus*, L., *Thalictrum flavum*, L., *Ranunculus repens*, L., *Stellaria aquatica*, Scop., *Corylus Avellana*, L., *Zannichellia palustris*, L., and *Cladium Mariscu.*, Br. With a similar distribution in the Old World, eight species (*Bidens tripartita*, L., *Myosotis cæspitosa*, Schultz, *Suæda maritima*, Dum., *Ceratophyllum demersum*, L., *Sparganium ramosum*, Huds., *Potamogeton pectinatus*, L., *Carex paludosa*, Good., and *Osmunda regalis*, L., are found also in North America. Of the remainder, ten species (*Nuphar luteum*, Sm., *Menyanthes trifoliata*, L., *Stachys palustris*, L., *Rumex maritimus*, L., *Rumex Acetosella*, L., *Betula alba*, L., *Scirpus pauciflorus*, Lightf., *Taxus baccata*, L., and *Isoetes lacustris*, L.-extend round the north temperate zone, while three (*Lycopus europæus*, L., *Alisma Plantago*, L., and *Phragmites communi*,) Trin.), having the same distribution in the north, are found also in Australia, and one (*Hippuris vulgaris*, L.) in the south of South America. The list is completed by *Ranunculus aquatilis*, L., distributed over all the temperate regions of the globe, and *Scirpus lacustris*, L., which is found in many tropical regions as well.

The various physical conditions which necessarily affected these species in their diffusion over such large areas of the earth's surface in the course of, say, 250,000 years, should have led to the production of many varieties, but the uniform testimony of the remains of this considerable pre-Glacial flora, as far as the materials admit of a comparison, is that no appreciable change has taken place.

I am unable to carry the history of any existing species of plant beyond the Cromer deposits. Some of the plant-remains from Tertiary strata have been referred to still living species, but the examination of the materials, as far as they have come before me, convinces me that this has been done without sufficient evidence. The physical conditions existing during even the older of the Tertiary periods were not suitable to a flora fitted to persist in these lands in our day, even if the period of great cold had not intervened to destroy them. And in no warmer region of the earth do these Tertiary species now exist, though floras of the same facies occur, containing closely allied species. The sedimentary beds at the base of the Glacial epoch contain, as far as we at present know, the earliest remains of any existing species of plant.

It is not my purpose to point out the bearing of these facts on any theoretical views entertained at the present day: I wish merely to place them before the members of this Section as data which must be taken into account in constructing such theories, and as confirming the long-established axiom that by us, at least, as workers, species must be dealt with as fixed quantities.

SECTION H

ANTHROPOLOGY

OPENING ADDRESS BY SIR GEORGE CAMPBELL, K.C.S.I., M.P., D.C.L., F.R.G.S., PRESIDENT OF THE SECTION.

I FEEL much diffidence in taking this chair, for, though in former days I used to pay a good deal of attention to what was then called ethnology, I have been for many years immersed in perhaps more exciting but, I am afraid, less satisfactory occupations; and I feel that I am very far behind in scientific knowledge and scientific methods. I only venture to address you because I take for my subject practical, rather than scientific, anthropology; the study and cultivation of the creature man as he exists, rather than that branch of the subject which seeks to inquire into his origin and development. Intensely interesting as are inquiries into the origin of man, it must be admitted that our knowledge on the subject is still very limited and our progress slow; that we have not yet got hold of the missing link, and scarcely know whether the flint implements are the work of man or of some earlier intelligent creature. We are hardly on firm ground till we come to man very much in the form in which we now have him, and even already divided into the principal varieties which exist to this day. I now then invite you to approach the subject rather as practical agriculturists deal with the subject of horses and cattle than as scientists who trace these animals to very ancient prehistoric types; and in dealing with man from this point of view I am emboldened by the consideration that here also science has not yet completely conquered the field, and that very much is open to those who bring to it only a quick eye and careful observation. I think it can hardly be doubted that, in distinguishing well-marked types of humanity, the eye is after all the easiest and perhaps the safest guide. With that alone one can recognise the unmistakable differences of colour, size, facial features, set of the eye, character of the hair, and one or two other features by which the physical characters of different types of humanity are varied. On the other hand, when we come to nicer and more subtile distinctions, especially among the mixed races which occupy most of the world, we must confess that anthropometric science as applied to craniology, &c., gives us results only partially conclusive. I have an unusually narrow head. I can hardly be fitted with a hat without making the hatter elongate it; my next brother has so remarkably broad a head that he cannot be fitted without altering a large hat the other way: and so I think it is in many families and races, as any one who tries to puzzle out craniological results will find.

So again as regards other guides to race. It is admitted that language is not always a safe guide, but still it is a very important element in ethnological inquiries, especially among primitive races. I have paid some attention to that, and my impression is strong that language tests of race are to be found in the few simple elementary words and forms which any observer can easily master and examine, and not in the higher developments of the language, which are generally much intermixed with and influenced by foreign elements. I roughly put together a few dozen test words, &c., which we found very efficacious in India. Take English, too: the origin of the race is found in the lower and monosyllabic words, though the majority of the English words in a dictionary are Latin and French.

There is another race-guide which requires much care and some scientific accuracy, though not of what we should call a properly anthropometric character—I mean laws, customs, and habits. Like language these too may be varied by foreign influences, but I incline to think that they are more important for our purposes than has always been recognised, and are at least as persistent as, perhaps more persistent than, language. At any rate, they are certainly most important as affecting the modern history and cultivation of man; and while some laws and customs require scientific study, many habits and practices are on the surface, and open to the observation of every intelligent observer. I might class food and drink among such habits, as being those which bear most directly of all on physical

development. For instance, one scarcely realises till one goes to China how important is the cow as pre-eminently an Aryan animal, the early sacredness of which was founded upon uses almost ignored by other great races, such as the Chinese. The Chinese, again, who will not touch milk, and reject some other food which we think among the best (pheasants, for instance), make constant and large use of food which we reject, such as puppies and rats. It is most interesting to inquire whether there is any foundation for either class of prejudices.

Among other habits and institutions well worthy of observation I might cite marriage and the family descent, through the female or through the male, the forms of small self-governing communities, and the tenure of land. Animals of nearly allied species seem to be divided by curiously sharp lines into polygamous and monogamous races. It is hard to understand why hares should be strictly monogamous, rabbits polygamous, partridges monogamous, pheasants polygamous, geese monogamous, ducks polygamous. We have yet to discover to which class man belonged before laws divided the race into two opposite camps in this matter. When we come to institutions and land tenure we approach the region of politics, but for my part I must at once say that, if we avoid mere party in politics, we anthropologists are called on to perform most important functions in the social politics of the day. What can be more important than to ascertain the effect on the race of modern urban life, of the increased use of meat, of the diminished use of milk, of the enormously increased consumption of tea, of the more constant use of the eyes and the brain, viewing these subjects in their broad general results, rather than from a merely medical point of view?

My view of the good work that may be done by the more popular methods in anthropology may be somewhat consoling to our countrymen generally, for they seem as a whole to be too busy for much science, and to be deficient in it. I see it was stated that we have to get anthropometric instruments from abroad. But on the other hand our opportunies for observation far outrival all others. In our vast Empire we have every race, and every shade, every stage of progress, from the lowest to the highest; every institution and every method of living. As rulers, as explorers, as merchants, as employers of labour, as colonists, we come into the nearest contact, and have the most intimate relations with almost every people and every tribe on the face of the earth. We are indeed a people who, if we make but the most moderate use of opportunities, may bring together such a mass of knowledge of mankind as to leave nothing wanting. Surely then in this country anthropology is no mean subject.

Both in regard to the greatness of our dominion, the vastness of the population, and its infinite variety, India is by far the greatest of our fields, as it is that in which we have the most complete and effective official machinery. India is remarkable not only for its many countries, climates, and races, but also for the division of the populations into what one may call horizontal strata. There, under the caste system, every rank, occupation, and profession represents in some sort a race, and that in enormous variety. Whatever infiltration of blood there may be, every caste in India is at least as much a peculiar and separate race as were till lately Jews or gipsies in our own country, and more so. Every one of them has, too, its own institutions, its own rules of marriage and inheritance, its own laws and customs; and I need scarcely add that outside this Hindoo agglomeration of many races there are the various aboriginal races—also in great variety, and in a state of excellent preservation—tribes not of one family of the human race, but of almost every great family, from the purest Aryans of the north-west to what I may call extreme Mongolians in the east, and primitive blacks in the centre and south.

In truth, my experience of that great anthropological field India is my excuse for sitting here to-day. It has been my fortune to serve in very many parts of that great country, and, so far as my scanty acquirements permit, I have always taken great interest in, and inquired much about, the races and varieties of the peoples; and I think I may claim this, too, that ever since I have been a good deal absorbed in politics, in all the travels I have made in several parts of the world, in Eastern Europe, in America, and elsewhere, I have never wholly forgotten my ethnological proclivities, and have pried about a good deal to pick up information regarding the various races and tribes.

As India is in some sense an epitome of the world, so I may also say that the last provinces I administered, those forming the Government of Bengal, are or were an epitome of India. At that time the whole of Assam and the eastern frontiers were under Bengal, and we certainly had a very much greater variety of races than any other province in India—perhaps I may say than any other country in the world. Among the more advanced races, besides the whole of the well-marked Bengalee nationality we had some twenty millions of Hindustanis on the north, the Ooryahs on the west, and the Assamese on the east; then of the Indian aboriginal races, while in other provinces they have but scanty hill tribes, counted by thousands, we have in the western districts of Bengal may millions of these aborigines, settled, comparatively civilised, a fecund, colonising, and migratory people; we have them in endless variety of both the great aboriginal families, the Dravidian and that now generally known as the Kolarian. Partly in the Central Provinces and partly in Bengal, it has indeed been my lot to administer the whole of what I may call "aboriginal India." I may here mention that the several aboriginal Dravidian tribes of this tract speak languages clearly Dravidian in their roots, and yet for the rest so distant from the cultivated Dravidian languages that the common origin must be very ancient indeed. But no one who sees these people can doubt their non-Caucasian character; and that may go far to settle the question whether the Dravidians of the Peninsula are of Caucasian origin, or non-Caucasians overlaid by an Aryan over-crust.

Again, on the north and east we have some forest tribes which may or may not be related to the aborigines of the interior of India. But as soon as we get into the hill country we meet with every form of what may be called the Indo-Chinese type—all the way from the frontiers of Nepal on the north, along the Eastern Himalayas, round both sides of Assam, and then on to Maneepore, the Chittagong hills, and the Burmese country. Here and there in this great extent of country we have many unclassed races with peculiar languages and institutions of their own—some very savage, others far advanced in civilisation. Among the latter I might mention, for instance, the Khassyahs, a very peculiar people with highly developed constitutional and elective forms of government, and also specially interesting as exhibiting far the best specimen of which I have anywhere heard of the matriarchal, or perhaps I should rather say matri-herital, system fully carried out under recognised and well-defined law among a civilised people. The result of observation of the Khassyahs has been to separate in my mind the two ideas of matri-heritage and polyandry, and to suggest that polyandry is really only a local accident, the result of scarcity of women; as, for instance, in some parts of the Himalayas, where the hill women are in great demand in the adjoining plains, and the hill men are obliged to be content with a reduced number of women. Among the Khassyahs, on the other hand, there is no polyandry (so far as I have been able to learn) though there is great facility for divorce; and heritage through the female becomes quite intelligible, I may say natural, when we see that the females do not leave the maternal home and family and join any other family, as do the Aryans. They are the stock-in-trade of the family, the queen bees as it were; they take to themselves husbands—only one at a time, and if he is divorced they may take another—but the husband is a mere outsider belonging to another family. The property of the woman goes in the woman's family, the property of the man in his own maternal family. It should be added, however, that in these maternal families, though the heritage comes through the female, the males rule, as they ought to in all well-ordered communities.

When I administered the Government of Bengal I did the best I could to obtain a classification of our many races, and a comparison of the languages brought together under my system of test words, and officially published in a large volume. We owe to the unrivalled experience of the late General Dalton a mass of information regarding the western aboriginal tribes, comprised in his great ethnological volume and many other publications; and more recently that very distinguished Indian officer, Mr. A. Mackenzie, partly a Scotchman and partly a Birmingham man, has brought together in his "North-East Frontier of Bengal" a full and most interesting account of the eastern tribes. Now I am happy to say that one of my old fellow-workers in Bengal, who at present most worthily and well administers the government of that province, has undertaken, through Mr. Risley, a much greater work than any of us have yet attempted, viz. a general survey of the whole people, not only as regards their physical characteristics and languages, &c., but also (and this is the newest and most important part of the undertaking) as regards their institutions, laws, and social rules.

It is hoped that, by obtaining accurate information of this kind regarding the many races, tribes, and castes of these great provinces, a flood of light may be thrown on the social history of the human race. It is a very great undertaking, but successfully carried out must have very great results. I can conceive nothing more important and interesting, and only hope that something of the kind may be attempted for India as a whole. Some of the most important castes, the Brahmins for instance, are so widely spread that we can hardly realise their position without extending the survey over India. In Bengal I think they are little agricultural, while in some provinces they are among the best of the agriculturists.

I could well wish that we had systematic inquiries of this kind nearer home. Europe is almost as good an anthropological field as India, and in our islands there is still very much room for investigation. In my own country of Scotland, after much asking, I have never been able to get any information who the Aberdonians are, and what is the language they speak, so different in its forms and intonations from the rest of Scotland. In England some most interesting maps might be made if it were only to trace the letter *h*, showing where it begins and where it ends. I have a belief that though languages may be changed and cease to indicate races, there is a great racial persistency in the letter *h* or the absence of it. The Scotch and the Irish have adopted the English language, but no Scotchman or Irishman was ever in the smallest degree wanting in aspirates—an Englishman might perhaps call them hyper-aspirators. The greater part of England, on the contrary, is equally persistent in the dropping of *h*'s. The whole subject is most interesting, not only in regard to the use or omission of the *h* by various races, but also on account of the very singular—I may say phenomenal—tendency of so many of the English neither to maintain nor to abandon the *h*, but simply to reverse the written language, omitting the *h* where it is written, and putting it in where it is not, in a peculiarly aggressive manner. It has been noticed, with truth, that we seem legitimately to drop the *h* in almost all words that come direct from the Latin, as "hour," "heir," "honour," yet in the Latin we pronounce the *h* fully. Is the spoken language the true tradition? Can it be that, while the Greeks spoke in aspirates which they did not write, the Romans clipped those which they did write, and that the modern Englishman combines the practice of these two famous races? Or is there any foundation for what I can call no more than a conjecture, viz. that the real English is that spoken by the Scotch, and that the corruption of the *h*'s is French brought in by the Normans? If a language map showed the clipping of *h*'s to be coincident with large Norman settlements, that might be so. Perhaps a few hundred years ago it was the aristocratic thing to clip the *h*'s, and the fashion may have gradually gone to the lower classes like the swallow-tailed coat worn by the typical Irish peasant, while the upper classes have been partially reformed back to true English by contact with the Scotch—only partially though, for they still say "wēn" and "wāle" instead of "when" and "whale," to say nothing of "idear" and "Indiar."

This, however, is a digression. I am afraid I have been long in coming to the main object of this address, viz. to recommend the systematic and scientific cultivation of man—what I may call "homi-culture," in the same sense as "oyster-culture," "bee-culture," or "cattle-culture"—and that with a view both to physical and mental qualities. It seems very sad indeed, that, when so much has been done to improve and develop dogs, cattle, oysters, cabbages, nothing whatever has been done for man, and he is left very much where he was when we have the first authentic records of him. Knowledge, education, arts, he has no doubt acquired; but there seems to be no reason to suppose that the individual man is physically or mentally a superior creature to what he was five thousand years ago. We are not sure that under very modern influences he may not retrograde. No one doubts that, by careful selection and cultivation, cattle, vegetables, and many other things have been immensely improved. In regard to animals and plants we have very largely mastered the principles of heredity and culture, and the modes by which good qualities may be maximised, bad qualities minimised. Why should not man be similarly improved? It is true that the mind has a larger share in that which constitutes a man; but after all this is only a question of degree—the cultivation of the mind *does* enter very largely into animal-culture. I apprehend there is no doubt that the superiority for our purposes of shorthorns, black-polled, and other famous breeds of cattle is very largely due to placid and well-regulated minds, which enable them to take calmly a short and happy life, and to assimilate their food, differing in this very much from their restless and often vicious ancestors. Surely, then, if we only had the requisite knowledge, and, taking a practical view of life, could regulate our domestic arrangements with some degree of reason, rather than by habit, prejudice, and the foolish ideas cultivated by foolish novelists, man too might be greatly improved.

It may be admitted that we are not in a position to begin confident man-culture at once. Much study is first required and much knowledge must be accumulated before we can be confident in practice. The first thing that most strikes us in man, as compared with all domesticated and even most widely-spread wild animals, is the extremely small variation in man all over the globe. There are differences which seem large to us, but are extremely small from a more enlarged point of view. How enormous are the differences between different breeds of dogs, horses, and cattle! When we come to man the difference of which we make most is that of colour—a feature which we think quite trivial in animals. Who thinks very much more highly of a white than of a black cow, of a grey horse than of a black one? Our skilled eyes recognise variations of human feature, but they are so slight that the inhabitant of another planet would see no more difference than in the countenances of a flock of sheep. In size, compared to other animals, the differences are but slight. Probably there is no race whose average height really approaches six feet, and I doubt if any are on the average so small as five feet. In other physical features there are no considerable differences of formation whatever. Then as regards the mind we have yet to learn that there are very wide differences of mental capacity between different races. Very likely—probably, I may say—there are considerable variations, but they are not so wide as to be apparent without careful and accurate study. With the superficial knowledge we have, no one can say that Europeans, Hindus, Chinese, are born with brains superior or inferior to the other; and even in regard to the negro I do not know that it is yet shown that with equal advantages Negro babies might not grow up nearly or quite as intelligent as Europeans. I do not say that it is so, but only that the question has not yet been sufficiently worked out. The difference is not so radical as to be self-evident from the first. Still, such experience as we have and the analogies derived from domesticated animals both tend to the belief that there *are* considerable, if not excessive, variations in the qualities and capacities of different races of men.

It seems to me, then, that the first object to which observation and experiment should be directed is to ascertain how far the qualities which distinguish different races, peoples, castes, and families are congenital and hereditary, and how far the result of education and surroundings. The distinguished President of the Anthropological Institute, Mr. F. Galton, has done much to make a beginning of the study of hereditary qualities in man, but there is still much to be done. To begin with very rudimentary facts, we hardly know whether courage in man and absence of courage in women are natural or artificial qualities; whether right-handedness is natural or a very ancient fashion. Coming nearer to modern variations we do not know how far energy, enterprise, constructive power, and all the rest of it are qualities appertaining to particular breeds, like the qualities of pointers or greyhounds; or whether they are more the result of education and surroundings. What is the effect on mind or body of vegetable and animal food respectively, and of the use of one stimulant and another? Why do particular races affect particular stimulants? Why is the Northern European more especially given to spirits, and the Chinese and Indo-Chinese races to opium? Is there anything in the breed that enables Britishers to rule over Hindus, or is it only education? Why has a Chinaman some virtues which an Irishman has not, and *vice versâ*? All through, the most important inquiry is to sift out those qualities in regard to which we must look to improvement in the breed, and those which more depend on education, so that power may not be wasted by efforts in the wrong direction—by breeding for qualities which already exist, or educating where the breed renders a particular education hopeless.

We must try to learn the direction in which we are to work first, and then the methods by which we may effect improvements in the ascertained direction—whether it be in the direction of breed or in that of education.

Now to come to the practical modes by which effect might be given to some such ideas as I have ventured to suggest.

To begin at the beginning, I think that, while so much effort and so much science have been expended, perhaps not very fructuously, in inquiries into the origin of man, too little systematic attention has been given to the radical differences between the modern man and modern animals. For instance, in the matter of speech no one can doubt that dogs and elephants and seals understand a great deal of language. One cannot see the individuals of a pack of hounds answer to their names without being satisfied that they not only attach a meaning to a few rude sounds, but can distinguish niceties and refinements of language. Again, we know that parrots and other creatures can speak our language; but I have never seen the question whether any one creature can both speak and understand thoroughly worked out. Has it been carefully and thoroughly ascertained whether any animals really cry or laugh? Sir John Lubbock and others have given attention to the question whether, in habitation-building, and the like, bees and ants exercise an intelligent discretion or follow one unvarying hereditary instinct; but I do not think any distinct conclusion has been arrived at. Can any monkey or other creature be educated up to the point of putting sticks on a fire and cooking chestnuts? I am afraid that on all these subjects there has been nothing but very desultory individual effort.

Then as regards man-breeding. Probably we have enough physiological knowledge to effect a vast improvement in the pairing of individuals of the same or allied races if we could only apply that knowledge to make fitting marriages, instead of giving way to foolish ideas about love and the tastes of young people, whom we can hardly trust to choose their own bonnets, much less to choose in a graver matter in which they are most likely to be influenced by frivolous prejudices. As I am not preaching I need say no more on that—all that I could say is self-evident. But when we come to the very important question of the crossing of races there is very great need of scientific observation and experiment. Both the general knowledge that we have of humans and the analogy of animals tends to show the great benefit of the crossing of breeds. Anglo-Saxon is an awkward term. I do not stop to inquire whether it represents two races; whether the peasant of the Lothians is an Englishman and the peasant of the south of England a Saxon, or why one is superior to the other; but using the word English for the Teutonic inhabitants of these islands I think one can hardly doubt that the English breed crossed with a dash of Celtic blood produces a better animal than either of the parent races. Witness the people of many parts of Scotland, of Ulster, and, I believe I may also say, of Cornwall. It is the use of the Celtic blood as an alloy that makes me specially unwilling to see Highlanders, and even wild Irishmen, exterminated from these islands. It may be worse for all of us if that comes to pass.

There is a popular belief that the cross between an Englishman and a Hindu produces a race inferior to either. I very much doubt the fact. Owing to the caste system (and it prevails with us almost as much as with the Hindus) half-castes are placed at a very great disadvantage, but I doubt if they are naturally inferior; at any rate, the question requires to be worked out. I think we have the means of doing so if we systematically went about it. So again as regards the cross-breeds between whites and Negroes. There is so much prejudice on the subject in the United States that it is very difficult to arrive at the truth. Some people think that the stimulating climate tends to make the white race in America wear itself out, and that (apart from the present great immigration from Europe) it would be a real improvement to the American race if the whites were crossed with the more phlegmatic blacks, say, in the porportion of six or eight of white to one of black, which now exists in the States. However, that is their affair, but a very important question for them.

And this brings me to the effect of climate. Is it the fact that in course of generations settled in America the climate alters the British race—or perhaps I should say European races? What is the tendency of the very peculiar Australian climate? It has passed into a popular proverb that the European race cannot survive in India beyond the second or third generation; and the result of that belief has been of enormous practical importance, for no sort of colonisation has been attempted. Yet I wholly doubt if the belief can be supported by any facts whatever; it is one of those things that are universally believed because they have never been tried, and therefore cannot be contradicted. Till little more than fifty years ago Europeans were not allowed to settle in India. To this day opportunities for education and good up-bringing are very much wanting—the surroundings are most unfavourable to European children; yet a good many instances could now be quoted of Europeans brought up in India who are physically just as good as their parents. The mortality in the European orphan asylums is extraordinarily low. It is not at all certain that the race might not be adapted to the climate, especially as the cool hill regions are those least occupied by the natives, and most fit for many lucrative industries introduced by Europeans.

Coming to physical and mental education, I have already alluded to some of the subjects which urgently require attention, the most important of which is, I think, the effect of what we call civilised life, and especially urban life. It is impossible to see the crowded and inferior dwellings in which so vast a population live in towns, without room for the gardens which their fathers had, and without the space and recreations natural to man, and not to fear for the result on the race. I might also say more on the question of physical education and on that of a mental education so general as to leave no mere primitive jungle plants as a stock on which to graft improved varieties; a subject which is already engaging anxious attention. On many other questions to which I have briefly alluded I might enlarge, but I have detained you so long that I think you would prefer to get to business; and so I will conclude by recommending practical anthropology to your earnest attention.

NOTES

We have received the programme of the Finsbury Technical College for the session 1886-87. There is no change in the curriculum calling for remark.

On September 3 a banquet took place in Bologna to celebrate the 100th anniversary of the discovery of animal electricity in that city by Galvani.

The *Bund* announces that Prof. Forel, of Morges, in the Canton of Vaud, has discovered a natural gallery which goes right across the lower portion of the glacier of Arolla, in the Eringerthal, in the Valais. It constitutes a natural grotto in the heart of the glacier, and was explored to a distance of 250 metres (273 yards) by the Professor and some fellow-members of the Swiss Alpine Club from Geneva, Neuchatel, and the Canton of Vaud. The average width was from 6 to 10 metres, broadening out here and there to fully 25 metres; the height varied from 2 to 3 metres. At the spot where the party stopped, the cavern divided into two galleries, the exploration of which they reserved for another time. The glacier was found to rest direct on the ground.

According to a Kimberley journal, Dr. Holub's exploration party is making but little progress. The whole of the party had been down with the fever, which has been severe this year in the Zambezi region.

The captain of the steamer *Ardangorm* officially reports at Malta that at 1 p.m. on August 30, in clear, calm weather, when about 14 miles north of Galita, a small island between Sardinia and Tunis, he noticed that the eastern and highest peak of the island appeared to be in eruption, while smoke resembling that ascending from Mount Etna was ejected at intervals from the crater.

The *Pioneer* of Allahabad states that news dated last April has been received from Mr. Carey, who is travelling from Leh towards China. He was then at Lob Nor. His course from Leh was south-eastward into Western Tibet, and then due north to Khotan, whence he made the Tarim River. After an excursion northwards towards the Baba Kul Lake he returned to the Tarim River, and followed it to Lob Nor. He is said to have probably entered Northern China before now.

One of the projects formed by M. Paul Bert before leaving France as Resident-General in Tonquin and Annam, was the

formation of an Academy similar to that planned by Napoleon I. for Egypt. M. Bert has now issued a decree establishing the "Tonquinese Academy." The preamble sets out that it is desirable to revive in the country, which has been disturbed for so long a time, the taste for literature and science, and to preserve to the people the vestiges of its glorious past; as well as to collect the scattered evidences of its ancient splendour. The decree then goes on to provide that the seat of the Academy shall be at Hanoi, and that its functions shall be to investigate and collect everything of interest, from any point of view, relating to Tonquin, to preserve ancient monuments, to initiate the people into the knowledge of modern sciences and civilisation, by translating and publishing in the Annamite language *résumés* of European works, to translate into French extracts from the more important dynastic annals of Tonquin, as well as other works to be selected by a Commission, to aid in forming public libraries in the principal towns, and a national library at Hanoi, to publish a monthly bulletin in which scientific and other questions shall be treated, and to put itself in relations with other Oriental Societies in Europe and Asia. The Academy is to consist of forty members and an unlimited number of correspondents. The dignity of *Ham-lam* is to be conferred by the Resident-General. Various degrees are to be given to Tonquinese, and these are to be marked by a medal or emblem to be worn on the dress. Political questions are not to be discussed.

WE regret to learn that difficulties arising out of the reorganisation of the Imperial College of Engineering, Tokio, have resulted in the loss to the new University of Japan of the services of Prof. T. Alexander.

MR. R. JASPER MORE, writing to the *Times*, from the House of Commons, on the subject of "Science for the Masses," inquires why some of the 600 papers which are not read before the British Association should not be delivered as lectures at the schools or public rooms of the West Midland district, where "large and appreciative audiences would have been found, and a foundation laid for the objects of the British Association." "A few words spoken," he says, "in a familiar manner to working-men and others by members of the British Association would tend to make that taste for natural science the absence of which Sir John Lubbock deplores."

AT the last meeting of the Entomological Society of London, on the 1st inst., Mr. C. O. Waterhouse called attention to the various reports which had lately appeared in the newspapers of the discovery of the Hessian Fly (*Cecidomyia destructor*) in Britain, and inquired whether any communication on the subject had reached the Society. The Rev. W. W. Fowler stated that he had been in communication with Miss Ormerod on the subject, and that she had informed him that neither the imago nor larva of the species had been seen, and that the identity of the species rested on the supposed discovery of the pupa.

PROF. BRUN has published in the *Archives de Genève* an interesting study on the so-called lightning holes to be found in the High Alps. He and other investigators have found them at heights of from 3348 to 4000 metres, or between 11,000 and 13,000 feet above the sea-level. Usually they are found on summits. Sometimes the rocky mass, which has been vitrified in the passage of the electric fluid, presents the appearance of small scattered pearls, sometimes of a series of semi-spherical cavities only a few millimetres in diameter. Sometimes there are vitrified rays going out from a central point to a distance of 4 or 5 inches. Sometimes a block detached from the mass appears as if bored through by a cannon-ball, the hollowed passage being quite vitrified. The thickness of this vitrified coating or stratum never exceeds a millimetre, and is sometimes not more than the quarter of that depth. The varying colours which it presents depend on the qualities and composition of the rock. The same may be said as to its transparency. On the Rungfischhorn the glass thus formed by the lightning is black, owing to the quantity of actinolite which the rock contains. It is brown on La Ruinette, the rock consisting of feldspar mixed with gneiss containing chloride of iron. Under the microscope these lightning holes display many interior cavities, which must be attributed to the presence of water in the rock at the moment of melting by the electric discharge. This vitrified material has no influence on polarised light.

THE captain of the steamer *Thessaly*, belonging to the Houston Line, writing to the owners of that vessel, notes a strange experience on his last voyage from Liverpool to Monte Video. On Thursday, July 1, at 11.35 p.m., the ship, which at the time was in lat. 0° 55′, long. 29° 34′ W., was suddenly and violently shaken and bumped, the shaking being accompanied by a loud, rumbling, metallic kind of noise. The first impression was that the ship was tearing the bottom out over hard rock, but knowing there was nothing in the neighbourhood she could touch, save St. Paul's rocks, and as they could not see land, the captain concluded the machinery was going to pieces. A report received from the engine-room, however, stated that there was nothing wrong there. The engineer had slowed down instantly, under the impression that something had gone wrong. The carpenter reported the wells all free. The shock lasted about a minute; no disturbance was visible on the water. About 8 minutes after the first shock, a second, not quite so severe, stopped the ship, which in the meantime had been going slowly. Subsequently they experienced a third shock—a slight one. The lead indicated 60 fathoms with no bottom. Being now satisfied that the shocks were caused by some submarine disturbance, the captain proceeded on his course. After steaming about 15 minutes, he experienced a fourth shock, only inferior to the first in severity and duration. After this all was quiet. During the shocks the compass cards were much agitated.

WE have received a pamphlet by Prince Albert of Monaco describing the investigations which he has made during the past year in his yacht, the *Hirondelle*, into the Gulf Stream, and its relations with the coast of France. After referring to the interest which the Gulf Stream possesses for various branches of science, the Prince describes the knowledge of it possessed by the ancients, and the various investigations of modern times. The stream has been carefully studied by the Americans along their coasts, but our knowledge of it farther out in the Atlantic is more doubtful. Its influence on the French coasts has never been experimentally studied, and to this particular point the work on the *Hirondelle* was directed. 179 floats were thrown out at various places to the north-west of the Azores. These were of three classes—hollow copper balls, oak barrels, and ordinary bottles, there being ten balls, twenty casks, and 149 bottles. The various places of immersion formed a line about 170 miles in length. The conclusion which the Prince draws from the results so far is that as far as 300 miles to the north-north-west of the Azores, the Gulf Stream shows no tendency to flow towards the north-east, and even its tendency towards the east is scarcely pronounced. The pamphlet contains two charts, —one of the places of immersion of the floats, with the dates and hours, the other of the voyage of the *Hirondelle* from the time it left Lorient until its return.

THE session 1886 of the University College, Bristol, will begin on October 5. Lectures and classes are held every day and evening throughout the session. In the Chemical Department lectures and classes are given in all branches of theoretical chemistry, and instruction in practical chemistry is given daily in the chemical laboratory. Excursions to some of the

mines, manufactories, and chemical works of the neighbourhood are occasionally made. The Department of Experimental Physics includes courses of lectures arranged progressively, and practical instruction in the physical and electrical laboratory. Those students who attend the mechanical engineering course enter engineering works during the six summer months, and, in accordance with this scheme, various manufacturing engineers in the neighbourhood have consented to receive students of the College into their offices and workshops as articled pupils; the engineering laboratory is provided with a powerful testing-machine, and instruction in the use of tools is given in the workshop. Special courses in surveying are given, and excursions for field practice are frequently made. The Department for Geology, Biology, and Zoology includes various courses of lectures in all branches of those subjects, together with laboratory instruction. In the Botanical Department practical instruction is given by means of the Botanical Gardens, which contain upwards of 1000 specimens.

THE additions to the Zoological Society's Gardens during the past week include a Common Mole (*Talpa europæa*), British, presented by Mr. J. Scatcherd; two Hawfinches (*Coccothraustes vulgaris*), British, presented by Mr. W. Strutt; a Lanner Falcon (*Falco lanarius*), European, received; two Common Vipers (*Vipera berus*), British, presented by Mr. W. Robertson; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; two Common Marmosets (*Hapale jacchus*) from Brazil, three Indian Crocodiles (*Crocodilus palustris*) from India, deposited; a Mesopotamian Fallow Deer (*Dama mesopotamica*), four Long-fronted Gerbilles (*Gerbillus longifrons*), five American Milk-Snakes (*Coluber eximus*), an Argus Pheasant (*Argus giganteus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

CHANGES OBSERVED ON THE SURFACE OF MARS.—In the July number of the *Bulletin Astronomique* M. Perrotin gives a detailed account of his observations of Schiaparelli's "Canals" made during the months of April and May of the present year (NATURE, June 3, p. 110), remarking that their appearance differs little from that observed in the Milan astronomer's chart drawn in 1882, and that these markings appear to indicate the existence of a state of things, in the equatorial regions of the planet, which, if not absolutely permanent, at all events give evidence of considerable stability. But during the progress of the Nice observations of the "canals," some changes were noticed in the neighbourhood of the Kaiser Sea (Schiaparelli's Syrtis Major), which M. Perrotin has thought it worth while to put on record. During the earlier observations this part of the planet's surface was dark, like all the Martial "seas," and as it is represented in the chart. On May 21, however, the part of Syrtis Major extending from 10° to 55° of north latitude was seen to be covered with a luminous cloud forming regular and parallel bands, stretching from north-west to south-east on the surface, in colour somewhat similar to that of the continents, but not quite so bright. On the 22nd these cloud-like structures were more uniformly distributed than on the previous day; they were also seen on the three following days, but were noted to be of considerably diminished intensity. On May 25 the Nice observers noted the visibility of the isthmus which is placed in Schiaparelli's chart on the prolongation of Syrtis Major, below its junction with Nilus, in longitude 300° and north latitude 52°, and which had not hitherto been seen by them. M. Perrotin thinks it probable that these appearances are really due to clouds circulating in the atmosphere of Mars; at all events he concludes they arise from something connected with the atmosphere or with the surface of the planet capable of motion and of change in a comparatively short space of time.

A SUSPECTED NEW VARIABLE STAR.—In *Circular* No. 8 of the Liverpool Astronomical Society, Rev. T. E. Espin states that the star D.M. + 35° 4002 was observed by him on the night of June 26 last as a very red 8·5 mag. star. On August 29 it was again observed with the same comparison stars, and was found to be barely 9·5. There seems, therefore, reason for suspecting it of variation. Dunér calls this star "rouge-jaune foncé," spectrum III*b*. ! !, and identifies it with Pickering No. 36 (*Astronomische Nachrichten*, No. 2376), which seems improbable, as Pickering's place is 1m. 20s. *preceding* and 0° 7′ *south*. The place of D.M. + 35° 4002 for 1885 is R.A. 20h. 6m. 3s., Decl. + 35° 36′·1.

THE BINARY STAR OΣ 234.—In the *Astronomische Nachrichten*, No. 2743, Mr. J. E. Gore publishes elliptic elements of the orbit of this binary. The components are of magnitudes 7 and 7·4, and the star has always been a close and difficult object to measure even with large telescopes. Mr. Gore considers his orbit as provisional only, on account of the discordance of some of the recorded measures. The following are the elements:—

$P = 63{\cdot}45$ years	$\Omega = 124° \; 11'$ (1880·0)
$T = 1881{\cdot}15$	$\lambda = 71° \; 58'$
$e = 0{\cdot}3629$	$a = 0''{\cdot}339$
$\gamma = 47° \; 21'$	$\mu = +\, 5°{\cdot}67$

Mr. Gore states that these elements satisfy the observations fairly well from 1844 to 1853, and from 1870 to 1880, but in the years 1858–66 the discordances are considerable. The position of the star for 1880·0 is R.A. 11h. 24m. 20s., Decl. + 41° 58′.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *SEPTEMBER* 12–18

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 12

Sun rises, 5h. 31m.; souths, 11h. 56m. 11·0s.; sets, 18h. 21m.; decl. on meridian, 4° 7′ N.: Sidereal Time at Sunset, 17h. 48m.

Moon (Full on September 13) rises, 18h. 8m.; souths, 23h. 38m.; sets, 5h. 16m.*; decl. on meridian, 6° 34′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

M signifies maximum; *m* minimum.

THE RECENT EARTHQUAKES

THE earthquake record of the past week is a long and disastrous one. An earthquake of wide area and extraordinary intensity took place soon after 10 o'clock on the night of August 31, throughout nearly the entire portion of the United States east of the Mississippi, shocks being felt from the Gulf of Mexico northwards and from the Mississippi eastward to the Atlantic. The shocks were especially severe at Montgomery (Alabama), Cleveland (Ohio), Meadville (Pennsylvania), Raleigh (North Carolina), and Indianapolis (Indiana). In New York, Washington, Detroit, Milwaukee, Cincinnati, Louisville, Chattanooga, and other places severe undulations were felt. The shock was light at Chicago, and west of the Mississippi at Omaha, Ogden, or San Francisco no disturbance was felt. The bounds of the disturbed area are thus roughly defined to be the Mississippi, the Atlantic, the Gulf of Mexico, the Lakes and the St. Lawrence. Georgia and South Carolina appear to have been the most severely visited of all the States. At Augusta, in the former State, there were ten distinct shocks between 9.15 and 10.45 p.m., and the streets were filled with the terrified population. At Savannah five shocks were felt. Sharp shocks were also felt in New Jersey, and vibrations as far north as Philadelphia. Prof. Newcomb, of the *Nautical Almanac*, Washington, reports that the first shock occurred at 9.53.20, and the second at 9.54 30, lasting until 9.59. The Signal Service Bureau at Washington reports that four distinct shocks were felt there. The first began at 9.54, and lasted 40 seconds, the second at 10.0.4, the third at 10.10, and another at 10.30. Charleston, in South Carolina, suffered most severely,—the streets were blocked with fallen buildings, telegraph poles, and tangled wires. The population spent the night in the streets. As usual after violent earthquakes, fires broke out. The principal business quarter and two-thirds of the dwelling-houses have been destroyed, and the town was isolated from the outside world, the bridges and railroads being all destroyed. Sullivan's Island, a watering-place near Charleston, was submerged by a tidal wave. At Columbia, in the same State, ten distinct shocks of earthquake were felt, the last at 10.20 on the morning of the 1st inst. Fresh shocks were felt in the afternoon of the 1st at Augusta, Charleston, and Columbus, and during the same day throughout North and South Carolina and Georgia, and many fissures opened, emitting fresh water, white sand, and blue mud from a great depth. At 11.55 on the night of the 1st another violent shock in Charleston brought down several houses. Since that date, shocks of more or less violence have continued up to the present in the States above-mentioned.

This earthquake is believed to have disturbed a greater extent of territory than any earthquake on record. Twenty-two States, covering an area of a million square miles, were affected. Toronto and London in Ontario are said to have felt some symptoms of disturbance. The natural phenomena accompanying the earthquake are curious. The fissures in the earth, whence the sulphurous fumes arise, are not confined to Charleston itself, but are found for miles round the town. From these fissures is exuded sand, white in some places, and red in others. From other openings brackish tepid water has been spouted from 15 to 20 feet high. These fissures are not made by the sinking of the ground, but by the tearing apart of the earth's crust. Sometimes they are 20 yards long, and they are of uncertain depth. They could be seen to widen and contract during the shocks, and sand, water, and an unfamiliar substance of an oily paste character was expelled. After these ejections mound-like cones remained. The water in the wells was observed to rise and fall. At Summerville, the holiday resort of the people of Charleston, detonations were heard about once in ten minutes in all directions, but they appeared to have no relation with the earthquake shocks. There are some doubtful reports of flames being seen proceeding from the ground. The atmosphere during the earlier phenomena was oppressive, and so still was the air that the lamps burned out of doors for hours without flickering. A violent shock which visited part of South Carolina at 11 o'clock on the night of the 5th, was followed after an interval of five minutes by two brilliant meteors which shot across the sky from north to south. A curious occurrence is reported by the Correspondent of the *Times*. He says that on the 2nd inst. at Charleston "two showers of morsels of flints, abraded by mechanical action, were noticed, some having been recently fractured. The first shower fell at 7.30 a.m., and the second at 11." At the Signal Office at Washington the self-registering wind-vane shows a horizontal mark preceding and subsequent to the shaking, denoting a mild, steady, and almost invariable breeze. But during the 30 or 40 seconds of the most violent shaking, the marks indicate that the pencil point moved up and down the paper many times with great rapidity. The effect of the earthquake at sea is described by the captain of the steamer *Palatka*. He had just left Charleston, and was twelve miles off the harbour of Port Royal, in eight fathoms and a half, when he heard a terrible rumbling, lasting a minute and a half. There had been a heavy sea from the south-east, but when the rumbling began the wave-motion ceased, and the waters remained in a perfect calm until the rumbling ended, when the swell was again manifest. The wind was south-east and light, the weather cloudy, the barometer 30·01, and the thermometer at 80°. The ship's timbers vibrated strongly. No unusual meteorological conditions prevailed at Charleston before, during, or after the earthquake on the first day, according to the officer of the Signal Service. Profs. Mendenhall and M'Gee are investigating the effects of the earthquake at Charleston and Summerville.

Earthquakes are also reported from Malaga, where a severe shock occurred, on the 1st and morning of the 2nd; from Santa Cruz, in California, at 11.45 on the morning of the 2nd, where it is described as not violent, but long-continued; and from Smyrna, where several sharp shocks were felt between 10 and 12 on the night of the 31st, that is almost simultaneously with the American earthquake. A telegram dated the 5th inst., from Athens, reports that the shocks at Pyrgos have been renewed.

We have received several letters relating to the earthquake in the Eastern Mediterranean of the 27th ult. Prof. Forel, of Morges, writes that, as it extended at least from Alexandria to Berne, it covered an area of about 25° diameter. At Berne the seismograph of the Observatory marked the shock at 10h. 36m. 16s. local time, corresponding to 22h. 6m. 30s. Greenwich time. If, continues Prof. Forel, we admit, in accordance with the times recorded at Benevento, Fermo, Pesaro, and Zante, that the time of the shock at the centre was 22h. 1m. 20s. ± 70s. Greenwich time, then the seismic wave would have taken 5m. 10s. to reach Berne. It is said that the shock was felt at Alexandria 15 minutes after midnight, in which case progress in that direction was a little slower; put into Greenwich time, this would be 22h. 15m., or about 14m. for transmission from Zante to Alexandria. In Switzerland a small preparatory shock was felt in the Alps of Vaud, about 11 minutes before the Berne shock. Mr. Henry Simon, writing from Engelberg, in Obwalden, states that the shock was distinctly felt there as a swaying motion about 10.20 by several of the visitors and in different houses.

THE SCOTTISH METEOROLOGICAL SOCIETY

THE following is an abstract of the Report of the Council read at the meeting of the Scottish Meteorological Society held on July 22:—

Since the general meeting of the Society in March, the number of the Society's stations has remained the same.

The membership of the Society now numbers 719, being 7 more than at the meeting in March.

The preparation of a fourth paper on the climate of the British Islands, dealing with the monthly rainfall for the twenty years 1866–85, is now far advanced, and the results are practically and scientifically of great interest.

Much time has been spent in preparing for the press the whole of the observations of the Ben Nevis Observatory and those of the station at Fort William for the two years and a half from December 1883 to May 1886. The volume will shortly be in the hands of scientific men in all parts of the world. In connection with these valuable observations, the investigation of the important question of the bearing of the results on the weather of these islands is steadily advancing.

The position of the Ben Nevis Observatory on an elevated isolated peak, and the adjoining low-level station at Fort William being close to the sea, and on a bank sloping down to it, renders this pair of stations second to none anywhere yet established for the investigation of some of the fundamental facts of meteorology. Among the more important of these questions is the determination of the rate of decrease of temperature with height, and the rate of diminution of atmospheric pressure with height, for different atmospheric temperatures and sea-level pressures.

In these aspects the observations for the two years and a half from December 1883 to May 1886 have now been discussed. As regards decrease of temperature with height, it is shown to be at the rate of 1° F. for every 270 feet of ascent—a rate which closely agrees with the results of the most carefully conducted balloon ascents, and of those other pairs of stations over the world which are so situated as to yield trustworthy results for the inquiry. Ben Nevis Observatory and the Fort William station are among the very few such groups of stations that have yet been anywhere established.

In researches into weather phenomena and weather prognostics the most important point to determine is the normal difference between atmospheric pressure at the top of the Ben and at Fort William for the different atmospheric temperatures and sea-level pressures. This was empirically calculated from the observations, and thereafter the departures from the normals were ascertained for the five observations of each day since the Observatory was opened. The results showed a diminution of pressure from the calculated normals during the occurrence of high winds at the Observatory. The difference not unfrequently amounts to the tenth of an inch, and on one day the five consecutive observations showed differences of about a tenth-and-a-half inch. This diminution of pressure is doubtless occasioned by the winds, as they brush past the Observatory buildings, partially sucking out the air from the interior, thus lowering the pressure. This does not occur till the velocity rises to or exceeds the rate of 30 miles an hour.

It thus became necessary to recalculate the normals for pressure, using in the computations only those observations which were made when the velocity of the wind fell short of 30 miles an hour. This recalculation has recently been completed, and the inquiry as to the bearing of the Ben Nevis observations on the weather of the British Islands is being pushed forward.

The work at the Ben Nevis Observatory continues to be discharged by Mr. Omond and his assistants in a way that leaves nothing to be desired. Since the last meeting of the Society Mr. Omond has contributed a valuable paper to the Royal Society of Edinburgh, on the observations of wind force recorded at the Observatory. From a comparison of the results obtained from the registrations of Prof. Chrystal's anemometer, and the estimations of the force of the wind made by the observers on scale 0 to 12, he has determined the velocity in miles per hour for each figure of the scale, 1, 2, 3, &c. The highest figure for which the double observations were sufficiently numerous, so as to give a good average, was 8, which was found to be equivalent to a rate of 73 miles an hour. This velocity is of frequent occurrence; and as regards the higher force 11, which occasionally occurs, Mr. Omond estimates its equivalent at 120 miles an hour. Observations on the rain band have been undertaken by Mr. Rankin, the first assistant.

The hygrometric observations made by Mr. H. N. Dickson at the Scottish Marine Station and the Observatory have now been partially discussed by him, and the results submitted to a recent meeting of the Royal Society of Edinburgh. These results are of considerable value in determining how far Glaisher's factors, so largely used by meteorologists in hygrometric inquiries, may be used satisfactorily. As regards the remarkably dry states of the atmosphere, which are so prominent a feature in the climate of the Ben, Glaisher's factors are altogether inapplicable, and hence the hygrometric observations of the Observatory, therefore, will require a specially constructed set of tables.

The zoological work at the Marine Station has been carried on regularly. The principal work since March last has been the examination of the ova and larvæ of fishes. Endeavours have been made to obtain the early stages of as many species as possible, and as only a few species breed at one season, considerable success has been achieved. The results of this work have been communicated to the Royal Society.

Since the last meeting the Physical Department of the Scottish Marine Station has been actively engaged in carrying on observations of temperature and water-density in the Firth of Forth and the Clyde districts. Meteorological observations are continued at Granton, and the temperature of a number of rivers (the Thurso at three points, the Tummel, Forth at two points, Teith, Tweed, and Derwent) is being observed daily. Mr. Morrison has continued his monthly trips to Loch Lomond and Loch Katrine, where he has observed the vertical distribution of temperature. The work on the Firth of Forth, usually carried on solely by serial temperature observations made on the *Medusa* inside the Isle of May, has been supplemented by the captain of one of the Granton steam-trawlers, who was supplied with a deep-sea thermometer, and has been using it to good purpose in the North Sea from 30 to 60 miles off shore. The tidal variations of salinity in the estuary of the Forth were investigated by Dr. Mill and Mr. Morrison during a week's stay at Kincardine, and the result embodied in a paper read to the Royal Society of Edinburgh. Two trips of the *Medusa* on the Clyde supplied data for a paper which is presented to this meeting, as well as a quantity of observations not yet fully worked up.

The work of collecting and discussing the sea temperatures around the coast of Scotland is being carried on by Dr. Mill and Mr. Morrison. Since last meeting the Meteorological Council of London has lent all the sea observations made at the Scottish Coast-Guard Stations from 1879 to 1885; and observations of river temperature made by direction of the Duke of Sutherland and Mr. Boyd, Peterhead, have also been received. The Government Grant Committee of the Royal Society of London has given a grant of 50*l.* towards the completion of this work. Thermometers have been lent for use in the deep water off Shetland to Mr. F. Coulson, who is at present on a dredging trip in his yacht in that locality. The National Fish Culture Association of England, which has been in correspondence with the station for some time as to physical observations, has now commenced operations at several light-ships and on board the mission-smacks in the North Sea.

Mr. John Murray, of the *Challenger* Expedition, made a communication on the extent of the areas of the different mean annual rainfalls over the globe. He had been led to undertake this inquiry so as to find out the amount of material carried down from the land to the ocean, and which went to form ocean deposits. The amount of rain that fell upon the surface of the globe annually was estimated at about 34,000 to 35,000 cubic miles. Taking the inland drainage areas disconnected with the sea, such as the Sahara Desert, it is found that 77 cubic miles of rain fell upon these surfaces, which must be regarded as equivalent to the amount of evaporation. The Americans had calculated that 99 million millions of cubic feet of rain fell annually over the Mississippi drainage area. Calculating the outflow of the river, they estimated that only one-fourth of that water reached the ocean. By extending their inquiry over large areas, it was hoped that it would be made of some practical importance.

Dr. H. R. Mill, of the Scottish Marine Station, read a paper on the temperature of the water in the Firth of Clyde and its connected lochs. The configuration of the water system was explained by means of a bathymetrical chart. Roughly speaking, the Firth of Clyde contained two tracts of deep water—one in which the water is over 70 fathoms deep, running up Kilbrannan Sound, and the other rather deeper between Arran and Ayrshire—uniting with the first at the north of Arran, and continuing up Loch Fyne to near Ardrishaig, attaining its greatest depth off Skate Island, near Tarbert, where it is 107 fathoms. These tracts of deep water are separated from the Atlantic by a broad plateau, which extends between the Mull of Cantyre and Girvan, and rises to within 25 fathoms of the surface. There are also three shallow lochs—Gareloch, Holy Loch, and Loch Ridden; and four deep lochs—Upper Loch Fyne, Loch Goil, Loch Strivan, and Loch Long—which are shut off from communication with the outside waters by barriers rising in some cases to within a few fathoms of the surface. Dr. Mill then gave an account of the temperature in each of the regions as were ascertained during trips of the *Medusa* in April and June. He omitted, he said, discussing in detail the individual observations until fuller investigation gave the data for a general theory. In April, surface temperature over the whole Clyde district varied only from 42° to 45°, and the temperature at considerable depths had a range of not more than half a degree—41°·3 to 41°·8. The warmest water was found on the barrier plateau at the south end of the firth, and outside it, the deep lochs came next, and then the deep open basins. In all cases the temperature fell gradually, proceeding downwards for about 10 or 15 fathoms, and then remained constant to the bottom. By June a considerable heating of the surface-layers had taken place, and the different regions had undergone changes to a very different extent. The shallow lochs had been heated apparently from the surface and from the bottom; the greatest rise in temperature was found beyond the plateau, then in the deep open basins, and the least in the deep lochs, one of

which, Loch Goil, was only half a degree warmer than in April. The range of surface temperature in June was from 45° to 53°, and of bottom temperature from 42° to 47°·3, according to locality. Constant temperature to the bottom commenced at a much lower depth than in April. In the upper basin of Loch Long, which was discussed with more fulness, the surface-temperature was 48°·4, at 10 fathoms it was 44°·2, and from 55 fathoms to the bottom at 70 fathoms it was 44°. But between 10 fathoms and 55 fathoms the water was colder than at either of these points, reaching its lowest temperature of 42°·8 at 20 fathoms. It thus appeared that a lenticular mass of water floated between the warmer strata, the opinion as to the cause of which was meantime reserved until further light can be thrown on the phenomenon. In the Clyde district, Dr. Mill said, physical configuration is the determining cause of differences of temperature, and it appears that as the season advances, warmth descends from the surface everywhere by conduction, and travels inward from the sea by conduction and convection. The study of water climate, he said, was likely to lead to important results, but it must be carried on by a large number of observers, who would note the temperature of rivers and of falling rain, before any degree of completeness could be obtained. The paper was illustrated by a series of admirable charts.

SCIENTIFIC SERIALS

THE *Journal of the Franklin Institute*, August.—Capt. O. E. Michaelis, the applications of electricity to the development of marksmanship. This is the conclusion of an interesting paper on chronoscopic and chronographic methods, illustrated by cuts of recent instruments.—W. Lewis, experiments on transmission of power by gearing (conclusion of the discussion).—F. Lynnwood Garrison, the microscopic structure of car-wheel iron.—G. Richmond, the refrigeration-machine as a heater.—C. Hoele, a method of designing screw propellers.—F. E. Ives, correct colour-tone photography with ordinary gelatine bromide plates. A proposal to reduce the sensitiveness of the bromide films to the blue and green rays, by introducing into a plate-glass tank mixtures of aniline colour solutions, chiefly yellow and red, in certain proportions, thereby equalising the sensitiveness throughout the range of the visible spectrum.—Joshua Pusey, suggestions towards a simplified system of weather signals, termed the index weather-signal system.—P. E. Chase, Herschel and Jevon on density of the ether.

Annalen der Physik und Chemie, vol. xxviii. No. 8, August 1886.—Prof. G. Quincke, electrical researches, No. xii., on the properties of dielectric fluids under strong electric forces. The dielectric constant of a number of liquids is examined by two methods, by attraction between two plane parallel plates immersed in the liquid, and by discharge of their charges through a galvanometer. High potentials were obtained by a Holtz machine, and measured by a long-range electrometer up to 30,000 volts. The results show that with high electric forces the dielectric constant is less than with lower electric forces; in other words, there exists an apparent tendency to saturation in inductive capacity. Measurements of the dielectric constant are always from 10 to 50 per cent. higher when made by the balance-method than those made by the condenser discharge method. In different dielectric fluids the spark-distance for the same difference of potentials is different, and always much shorter than in air. The potential requisite to produce a spark within a dielectric liquid increases with the spark-length, but at a slower rate. The strength of a steady electric current in a dielectric fluid increases more rapidly than the electromotive force which produces it; an exception, apparently, to Ohm's law.—L. Sohncke, electrification of ice by water-friction. Experimental proof that water becomes negatively electrified and ice positively electrified by mutual friction. The author thinks thereby to explain the origin of thunderstorms by friction of cumulus and cirrus clouds.—E. Edlund, researches on the electromotive force of the electric spark. He finds the counter-electromotive force of the electric spark to be divisible into two parts, one at each pole, that at the positive pole decreasing, and that at the negative pole steadily increasing, as the air-pressure is diminished. He regards this as explaining the anomalies of unequal heating of the electrodes.—W. Donle, contributions to knowledge of the thermo-electric properties of electrolytes. According to these experiments the thermo-electromotive force between two electrolytes, such as solution of sulphate of copper and sulphuric acid is approximately proportional to the differences of temperature of the points of contact; the proportionality varying in some way with the concentration of the solutions. The electromotive force is usually less with more concentrated solutions. Through the heated junction of a chloride and a sulphate the current flows from chloride to sulphate.—F. Auerbach, on the electric conductivity of metal powders. Precipitated silver was used. The author finds an enormous reduction when the density is increased by mechanical force.—R. Krüger, on a new method of determining the vertical intensity of a magnetic field. This method consists in sending an electric current radially through a horizontal copper disk suspended by a thin wire, and observing the rotation of the disk.—R. Maurer, on the ratio of the sectional contraction to the longitudinal elongation produced in rods of glue-jelly. The rods were made of gelatine and water, and of gelatine and glycerine. One of the methods was an electrical one, consisting in observing the change of electrical resistance on stretching. These jelly rods exhibit the phenomena of residual strains very markedly.—M. Hamburger, researches on the duration of the impact of cylinders and spheres.—Dr. K. Noack, on the fluidity of absolute and diluted acetic acids. Curious minima of fluidity are observed by the author, varying with concentration and with temperature.—W. Müller-Erzbach, the law of decrease of absorbing power with increasing distance.

SOCIETIES AND ACADEMIES

EDINBURGH

Royal Society, July 19.—Mr. Robert Gray, Vice-President, in the chair.—The Right Hon. Lord Rayleigh communicated a paper on the colours of thin plates. He has laid down on Maxwell's triangle of colours a curve representing the variation of the colours of thin plates as the thickness of the plates increases.—Prof. Dr. Fr. Meyer communicated a paper on algebraic knots.—Prof. Tait described Amagat's "manomètre à pistons libres."—Prof. C. G. Knott communicated a paper on the electrical properties of hydrogenised palladium. This paper contains the results of experiments on the resistance and thermo-electric properties of hydrogenium or hydrogenised palladium. Up to a temperature of about 200° C. no special peculiarity is noticeable; but at that temperature, or a little higher, hydrogen begins to escape from the wire, and this causes the particular specimen of hydrogenium to recover partially, if not wholly, its pure palladium characteristics. It is known that the resistance of a palladium wire charged with hydrogen at ordinary atmospheric temperatures increases at a rate almost strictly proportional to the amount of charge. The same law seems to hold at all temperatures up to 150° C., and in such a way that the *total* increase of resistance of a given palladium wire for a given rise of temperature is nearly the same at all charges; or the temperature-coefficient for any particular specimen of hydrogenised wire is practically inversely proportional to the resistance as compared with the resistance of the wire in its pure uncharged state. Just before the hydrogen begins to escape, the resistance begins to increase somewhat more rapidly than at lower temperatures; and this peculiarity is more marked in the specimens of higher charge. When once the hydrogen begins to escape, the resistance begins to fall off rapidly as the temperature rises to 300° C. At this temperature the wire cannot be distinguished from pure palladium. In the thermo-electric experiments, peculiar irregularities appear at the higher temperatures, which seem to be due to the fact that the hydrogenium wire is unequally heated, and that the hydrogen, which is almost completely driven out of the heated portion of the wire, returns partially as the wire is cooled down again. In all cases at temperatures below 150° C., the current is from pure palladium to hydrogenium through the hot junction, is probably proportional to the difference of temperature in each case, and is greater for the greater charge. Thermo-electrically, fully saturated hydrogenium lies between iron and copper at ordinary atmospheric temperatures. On the thermo-electric diagram the hydrogeniums of different charge are represented (up to a temperature of 150° C.) by a series of straight lines parallel to palladium, whose thermo-electric powers at 0° C. range roughly from − 600 (pure palladium) to + 1400 (saturated hydrogenium) expressed in C.G.S. units. (Compare Everett's "Units and Physical Constants," p. 151.)

In other words, the electromotive force in a circuit of palladium and saturated hydrogenium, the temperatures of the junctions being 0° C. and 100° C., is 20×10^4 C.G.S. units, or ·002 volts. The thermo-electric peculiarities of hydrogenium may be prettily shown by the following simple experiment. Let a palladium wire, by immersion to half its length in the electrolytic cell, be hydrogenised throughout that half length. Attach the ends of this seeming single uniform wire to the terminals of a galvanometer, and let a flame be allowed to play gently at the central point of the wire. A large current is at once obtained, which grows to a maximum, and then diminishes to zero as the temperature rises to a red heat. There is no such current during cooling. This spurious neutral point is due to the hydrogen being driven out of the heated portion, partly, no doubt, into the contiguous colder portions. By following up with the flame the ever-shifting point of separation between the charged and uncharged portions, we may repeat the experiment indefinitely until the hydrogen is all driven out of the wire, or until the distribution of hydrogen has become fairly uniform.—Mr. Thomas Andrews communicated a paper on the electro-chemical reactions between metals and fused salts.—Mr. H. N. Dickson communicated a paper on the hygrometry of Ben Nevis and the Scottish Marine Station.—Mr. J. T. Morrison read a paper on the temperature of Loch Lomond and Loch Katrine during winter and spring; also, a note on the surface temperature near a tidal race.—Mr. John Aitken gave further remarks on dew.—Prof. J. B. Haycraft gave a communication on the nature of the objective cause of sensation.

Sydney

Royal Society of New South Wales, July 7.—H. C. Russell, F.R.A.S., in the chair.—The following papers were read:—Further additions to the census of the genera of plants hitherto known as indigenous to Australia, by Baron Ferd. von Müller, K.C.M.G., F.R.S. The author gives the number of Australian plant-genera recorded hitherto as 2248.—Notes on improvements in the construction of reflecting telescopes by hand, and experiments with flat surfaces, by Mr. H. F. Madsen. The author showed an 18-inch speculum, and the glass tool with which it was worked. The latter was composed of three plates of 1-inch rough glass cemented to form a solid block, and worked to about one-quarter more convexity than the required concavity of the speculum, which was partly hollowed out at first by a leaden weight and emery. The speculum-glass was then ground by hand over the block, the two forming themselves into perfectly spherical surfaces having a high reflective power, and free from irregularities of less than 1/50,000 inch. The speculum, having now an absolutely true surface, was polished with emery upon pitch, it being uppermost, and moved round without pressure. The pitch-polisher had an improved graduation, the result being that, without side motion, the speculum was polished by hand for hours without producing the trace of a ring. Both polisher and glass having been regularly raised in temperature, were left together until cool, when ten minutes was required to give the true parabolic curve, the glass being simply revolved on the polisher, great care being taken to avoid the slightest inequality in temperature. Without the aid of machinery, it is doubtful if larger specula than 18-inch could be produced by hand. Mr. Madsen investigated the thickness of the silver film of a speculum by a novel optical method, and confirmed the late Dr. Draper's "chemical" estimate, viz. 1/200,000 inch. Two perfectly flat surfaces 5 inches diameter were taken and illuminated by a homogeneous yellow light of 1/44,000 wave-length, falling at an angle of 30° incidence (Brashear's colour-test), whereby a series of straight dark and coloured bands were visible. By silvering half the upper surface of one of these glasses the bands were displaced or broken at the edge, a distance of about $2x$ (x being the distance between two succeeding bands). The thickness of silver, δ, would be expressed by

$$\frac{\lambda\,(\text{wave-length})}{5} \sec 30 = 0{\cdot}00000525.$$

Several measurements gave less than 1/300,000 inch. Under the same optical methods the effects of heat and cold were rendered plainly visible and measurable. The true surfaces were placed on a 2-inch diameter wooden chuck; the light falling at 65° gave a uniform colour. On applying the finger without pressure upon the centre of the top glass, the colour changed to regular concentric rings, causing the glass to become concave by a measurable quantity. Placing the glass upon an iron support produced convexity (1/30,000 inch) in a regular curve. With a pressure of 8 lbs. on the centre, two wide bands of colour appeared, crossing in the centre, straining the glass in two directions, and destroying its figure. These experiments show how the defining power of specula and lenses is injured by temperature.

Paris

Academy of Sciences, August 30.—M. Émile Blanchard in the chair.—In the name of the Academy the President felicitated M. Chevreul on his hundredth anniversary, remarking that the case was unique in the annals of the Academy; even Fontenelle, although spoken of as a centenarian, having died shortly before reaching that venerable age. M. Chevreul replied with a few touching words of gratitude for the sympathy of his *confrères*, after which a telegram was read from the University of Kasan complimenting the patriarch of the scientific world on his long and laborious life, so fruitful in valuable contributions to the progress of the technical arts.—On a remarkable case in the problem of planetary perturbations, by M. F. Tisserand. In the case of two planets revolving round the sun, or of two satellites round their planet, in orbits slightly inclined towards each other, it is shown that even if the proper excentricity be null there may be a very sensible apparent excentricity. In other words, if the movement of one orb was originally circular and uniform, the perturbations caused by the other would transform this movement into one approximating to a Keplerian elliptical orbit with a uniform rotation of the long axis. These results are compared with those obtained by A. Hall and S. Newcomb for the Saturnian satellite Hyperion, in so far as its movement results from the perturbations caused by the larger satellite Titan.—On the atomic weight of germanium, by M. Lecoq de Boisbaudran. The atomic weight of this body, provisionally determined by M. Winkler at 72·75, and by the author theoretically at 72·28, is now found by M. Winkler to be 72·32. The law of proportionality between the variations of the atomic weight and those of the wave-lengths, a law already applied to gallium, here receives a fresh and important confirmation. It becomes at the same time highly probable that no appreciable error now exists regarding the atomic weights of cæsium, rubidium, potassium, indium, gallium, aluminium, tin, and silicium. In fact the wave-lengths and atomic weights of Cs, Rb, K, In, and Al have served to calculate spectrally the atomic weight of gallium (afterwards verified analytically), while the λ and atomic weights of In, Ga, Al, Sn, and Si have helped to determine spectrally the atomic weight of germanium.—Note on a reptile of the Permian formation, by M. Albert Gaudry. To this reptile, which was found by M. Bayle in the Permian beds of Télots, near Autun, the author proposes to give the name of *Haptodus baylei* (from ἅπτω and ὀδούς), the teeth adhering so closely to the maxillaries as at first sight to be scarcely distinguishable from them. In these rocks, where no animals higher than fishes were for a long time known to occur, there are now found four distinct types of Reptilia: Actinodon, Protriton, Stercorachis, and Haptodus.—Phosphorography applied to the photography of the invisible, by M. Ch. V. Zenger. Observing Mont Blanc after sunset in September 1883, the author noticed that the blue-greenish glow remained perceptible till 10.30 p.m.; hence he concluded that the ice on the summit mingled with carbonate of lime emitted a light like that of Lake Geneva, and that it might be possible to fix the image of the mountain at night by means of the phosphorescent light of the ice, which is highly actinic. On his return he projected the images given by the photographic lenses in the dark chamber on a glass plate covered with a layer of Balmain's phosphorus, just as such plates are prepared with collodion. After exposing it for a few seconds, he removed it in the dark from the chamber in order to place it in contact with a not very sensitive dry photographic plate. After an hour of contact in the dark, the image of the object appeared in all its details as in an ordinary case of photographic impression. Subsequent experiments tended to show that light may be absorbed, and afterwards slowly given back, and that images of objects invisible in the dark may be fixed by simple contact, or by the photographic apparatus. He found it useful to cover the plates with chlorophyll, as when thus prepared they become sensitive to all the radiations of the solar spectrum from the ultra-red to the ultra-violet.—Observations of Winnecke's comet made at the Obser-

vatory of Algiers with the 0.50 m. telescope, by M. Ch. Trépied. On August 23 the apparent position of this comet was :—

Algiers mean time.	Apparent Right Ascension.	Log. fact. parall.	Apparent Declination.	Log. fact. parall.
h. m. s.	h. m. s.		° ′ ″	
8 4 29 ...	13 21 11·65 ...	1·656 ...	− 3 2 31·8 ...	0·731

—On some non-linear differential equations, by M. Roger Liouville.—On the algebraic integrals of the problems of dynamics, by M. G. Kœnigs.—Notes were submitted by M. Martin on an apparatus reproducing the motions of the heavenly bodies, and by M. L. Hugo on the geometrical forms of the hailstones which fell in Paris on August 23.

Berlin

Chemical Society, July 26.—C. Liebermann, President, in the chair.—S. Gabriel has further examined isoquinoline obtained by the reduction of monochlorisoquinoline; it melts at 20°. He has also prepared some new derivatives of dichlorisoquinoline.—Biedermann has prepared some derivatives of parahydroxybenzylalcohol.—Raschig communicated a very interesting research on the nature of gold chloride. He has prepared nitrogen compounds corresponding to the three oxidation stages of gold, and these he has analysed by a new method; he points out the analogy between the iodides of nitrogen and gold fulminate and the analogous compounds obtained from gold chlorides and methylamine.—Prof. Pinner reported on the following communications received by the Society:—Clève, on naphthalenesulphonic acids and on the value of orientation determined with the help of phosphorus pentachloride.—P. Bradley, on thienylglyoxylic acid and its derivatives.—R. H. Mertens, on the nitration of di- and mono-methylaniline with dilute nitric acid.—R. Leuckart and E. Bach, on the action of ammonium formate on benzaldehyde and benzophenone; bases are produced, that from benzophenone having the composition $\left.\begin{matrix}C_6H_5\\C_6H_5\end{matrix}\right\rangle CH.NH_2$. Camphor also reacts with ammonium formate with production of crystalline compounds which, however, have not yet been further examined.—T. H. van't Hoff and Ch. M. von Deventer have studied the question of the temperature at which reaction takes place in chemical decomposition and the accompanying phenomena: first in the case of double salts, *e.g.* sodium ammonium racemate or copper calcium acetate; and secondly in the case of double decomposition, *e.g.* the decomposition of magnesium sulphate and sodium chloride with formation of astracamite and magnesium chloride, the reaction temperature in this case being 31°.—B. Tollens describes what he considers the best method for preparing formaldehyde.—Werner Kelbe and H. Stein have a paper on the products of the action of bromine on aqueous solutions of xylenesulphonic acids.—H. von Perger gives a preliminary account of the results obtained from the action of ethyl acetoacetate and ethyl acetonedicarboxylate on hydrazo-compounds.

Stockholm

Geological Society, May 6.—Baron Nordenskjöld gave an account of his researches on the atomic weights of certain rare terrestrial metals, pointing out the peculiar conditions under which they combine in some minerals. He further described the analyses of the dust which had fallen in 1883 in the Cordilleras, believed to be of cosmic origin, being connected with the much-discussed red glows in the autumn of that year. Baron De Geer expressed the opinion that the glow was a natural meteorological phenomenon, though very pronounced in 1883, whilst Prof. Brögger sided with the usual view of its being caused by the Krakatão eruption.—Dr. E. Svedmark exhibited a map of the district of Roslagen, near Stockholm, showing the lakes and valleys which were considered to be caused by the cracking of the earth's crust. He also corrected the reported discovery of basalt at Tolånga, in the province of Scania, which on closer examination had been found to be diabase accompanied by the formation of tophus.—Dr. F. Svenonius read a paper forwarded by Dr. H. Sjögren, on the mud volcanoes in the neighbourhood of Baku, in which locality he has for a long time sojourned, in order to prosecute geological researches. The volcanoes occur in a line along the Caspian Sea some 120 miles in length. One of the greatest mud cones as 1000 feet high, and the crater 2100 feet in diameter, viz. almost equal to that of Etna. Three violent eruptions have taken place this and last year. They were accompanied by severe emissions of fire, as, for instance, once by a column of are 50 feet in height, visible at a distance of 80 versts. There are also violent discharges of gas, which on one occasion, on being fired, produced a fire-column 20 feet in height. The discharge was so violent that the current could only be fired at a height of 7 feet from the opening. The changes which the surrounding rocks and mountains had suffered through the influence of these volcanoes were of the greatest interest.

EARTHQUAKE DISTRIBUTION

Alphabetical Catalogue of the Earthquakes recorded as having occurred in Europe and adjacent Countries arranged to serve as a basis for an Earthquake Map of Europe. By Joseph P. O'Reilly, C.E., Professor of Mining and Mineralogy, Royal College of Science, Dublin. *Transactions* of the Royal Irish Academy, Vol. XXVIII. "*Science.*" (Dublin, 1886.)

THE distribution of earthquakes may be studied either geographically or topographically—either along its broad lines in connection with the general physics of the globe, or in its smaller details with immediate and minute reference to local peculiarities. The field of inquiry is in both directions vast and comparatively unexplored. As regards what we may call circumstantial seismography, little has been done in the particular application of general principles to explain the apparent caprices of disturbances. These are innumerable and fantastic; yet, by patient observation, they can to a certain extent be brought within the range of strict physical reasoning. The laws of wave-motion, taken in connection with the facts of geological formation, will account for a good deal. Not, however, for all. Subterranean agencies introduce an element of uncertainty into the calculation which no diligence or ingenuity avails wholly to eliminate. Thus, in South America certain districts are observed to remain year after year, perhaps century after century, unscathed amid surrounding devastation. They are hence called "bridges," the disturbance seeming, as it were, to flow beneath them, like a river under a bridge. Prof. Milne suggests that their immunity may be due to the total reflection of earth-vibrations which would otherwise reach them (" Earthquakes," p. 141). An obstacle to the propagation of such is besides often interposed by faults and fissures. The partial repose of Quito is attributed to the frequency of cañons in its vicinity; as, similarly, the Capitol of Rome and the citadel of Capua were said to be protected by numerous deep wells or springs sunk round them.

"Bridges," however, cannot invariably be depended upon. Their privilege of safety is liable at any moment to be withdrawn. The peninsula of Caraya, for instance, forming the northern shore of the Gulf of Cariaco, was never known to be shaken until December 14, 1797; yet it has since had its full share of disturbance. The interior arrangement of strata was here doubtless subverted, and the barrier to the extension of shocks from the chalk-hills of the mainland to the slate-rocks of the opposite peninsula overthrown, by the violence of the blow which destroyed Cumana. Centres of disturbance, too, shift and travel in a way to defy anticipation; and the effects of the interference of earth-waves, to which some terrific catastrophes, as well as many apparent anomalies of rest or commotion, are ascribed, can rarely be calculated beforehand. Nevertheless, much knowledge of high value, both practical and theoretical, might be acquired by the continuous topographical study of earthquakes in countries exposed to their ravages. Prof. Milne states that in Japan (where, through his initiative, more has been done in this branch than in any other part of the world), although earthquakes occur there at the average rate of two a day, yet with proper care a building site may be chosen as free from shocks as if it were situated in Great Britain.

The publication now under review is, however, directed to a different and a wider purpose. Prof. O'Reilly had already compiled a "Catalogue of Earthquakes" for these islands (see NATURE, vol. xxxi. p. 351); he has now accomplished a similar task for the whole of Europe with the outlying districts along the Mediterranean and Black Sea shores, designed to form the basis of a map showing the larger geognostic relations of these phenomena. Without some such picture, he rightly observes, no geological map should be regarded as complete. The latter displays results; the former represents the forces at work to produce them. The importance of earthquakes in geological history is great and far-reaching. Their connection with the physical structure of a country is most intimate. Every one of its leading features is related to them, either causally or consequentially. The main lines of jointing and fissuring, with the inseparably associated strike of coast-lines, are, according to a view originated by our author, directly conditioned by the prevailing direction of earthquake shocks. Its correctness can be tested only by statistical inquiries such as those of which he here gives us a laborious example. Other questions of interest awaiting similar elucidation relate to seismic action with reference to coal-fields and to the progress of elevation or subsidence.

Fuchs gives many instances of shocks limited to or originating in carboniferous districts (" Vulkane und Erdbeben," p. 196), and explains them by the progressive decomposition of organic matters quickened by the admission of air in working the shafts. The resulting escape of fire-damp diminishes the volume of the beds; they give way with a concussion, and an earthquake ensues. Extremely curious, in this connection, is the close agreement between the curves denoting the monthly frequency of earthquakes and of colliery explosions pointed out by Prof. O'Reilly (*Trans.* R. Irish Academy, vol. xxviii. p. 297). Each shows a strong and precisely coincident maximum in March, while the earthquake maximum in November is less perfectly matched by a conspicuous increase, one month later, in the number of explosions. The analogy of the equinoctial maxima of auroræ and magnetic disturbances cannot fail to suggest itself; and there are other indications that seismic and magnetic perturbations are not wholly extraneous to each other. Both auroræ and earthquakes, for instance, distinctly gain in frequency during the half-year which includes our winter season and the perihelion passage of the earth; and there have been too many and too close coincidences between their occurrences to be purely accidental.

Sudden changes of level, especially depressions, are an ordinary concomitant of earthquakes. An internal collapse of the strata in some cases produces the shock; in others the shock ruptures supports or overturns foundations long unsound. Degradation by water has perhaps undermined them; contractions have taken place through cooling, through chemical action, possibly through slow evaporation. At last a crash comes, and a tract of land,

deprived all at once of its insecure props, settles down to a lower level, a forest perhaps subsiding into a lake, or the sea over-washing a stretch of shore.

Slower processes of change, however, are probably far more general and effective, and with these seismic relations are still in part obscure. Such changes depend, there is little doubt, upon variations of equilibrium between internal forces of expansion and external forces of repression. Where these are accurately balanced, the bounding surface of the earth remains unaltered; where subterranean heat gets the better of gravity, as through the denudation of large tracts, elevation ensues; where the weight of the superincumbent strata is augmented by deposition, there is slow subsidence. The effects of the earth's secular cooling must evidently, in the long run, be thrown wholly into the scale for contraction; and yet it is to them indirectly that the upthrusting of mountain-ranges is due. These might be compared to the folds and creases of a garment grown too ample for the shrunken body it covers. The terrestrial crust, indeed, is less easily adaptable than an old coat; not a wrinkle in it but represents a series of paroxysms, every one implying a greater or less amount of earth-shaking, past and present. The snap after prolonged strain, the shifting and twisting of rocks, the fissuring and faulting, the slipping and wrenching and grinding of tormented strata in the effort to satisfy the stresses put upon them, all result in earthquake action of the mechanical kind. Thus, mountain-making is essentially a seismic operation, not only while in progress, but in its effects during long subsequent millenniums. This is one chief reason why the lines of earthquake distribution follow so faithfully the general direction of mountain-ranges.

But besides those commotions which result from the catastrophic restoration of disturbed equilibrium, there are earthquakes of the volcanic or explosive class. This species has been defined as an "uncompleted effort to establish a volcano." Such abortive eruptions are occasioned, there is much reason to suppose, by the sudden formation of steam at great depths beneath the earth's surface. They arise where broken and disjointed strata facilitate the percolation of water to volcanic foci. A fractured crust and a plentiful aqueous store are their developing conditions. Hence their frequentation of sea-coasts. Prof. Milne remarks that most Japanese earthquakes originate in the Pacific, and that the steepest coasts are, on the whole, the most severely shaken; as is easily intelligible when we consider the violence of the dislocations necessary to produce them.

Earthquakes may then be broadly distributed, according to their kind, into two systems, now coalescing, now independent of each other. The explosive species follow volcanoes along sea-coasts, the mechanical sort are associated with mountain-ranges; all attend lines of weakness, and are more or less closely connected with the shrinkage by cooling of the terrestrial crust. Thus, every volcanic region is liable to earthquakes; though there are earth-shaken districts which are not volcanic.

The tendency to alignment in volcanoes has often been noticed: Prof. O'Reilly indicates a similar peculiarity in earthquakes, adding that the lines along which they range commonly approximate to great circles. This inference, or suspicion, can be verified only by detailed charting. There are great difficulties, however, in getting a true graphical representation of seismic activity. Not only deficiencies in records have to be contended with, but grave perplexities as to their treatment. They are fully admitted by our author. The number of shocks felt in a given spot is the criterion inevitably adopted; but these may vary to any extent in intensity, or may be the mere sympathetic reverberation of some distant catastrophe. The Lisbon earthquake of 1755, for instance, may quite possibly have shaken every square foot of the globe. The ideal seismic map would be one of earthquake origins, with their attendant areas of disturbance; but this is at present far from being attainable; and we can only acknowledge the indebtedness of science to those indefatigable workers who, like Prof. O'Reilly, promote knowledge by the best *present* means open to them.

OUR BOOK SHELF

Department of Agriculture, Washington: Third Report on the Chemical Composition and Physical Properties of American Cereals, Wheat, Oats, Barley, and Rye. By Clifford Richardson. (Washington, 1886.)

THIS Report is an important continuation of a most valuable work. The object in view is to obtain accurate information respecting the composition of the cereal grains produced in the various States. The grain analysed is in some cases the produce of seed issued by the Agricultural Department, but generally represents the ordinary crops of the district. A complete physical and chemical examination has been made of each sample of grain: the results are tabulated under the head of the State in which the grain was reared. The Report contains 77 analyses of different varieties of wheat grown in Colorado; 179 analyses of the kernel of oats, and 100 analyses of the husk; 57 analyses of rye, and 72 of barley. The extent of variation in composition, the relation of physical characters to chemical composition, and the influence of climate, are discussed. The results are further compared with those obtained by investigations in Europe. At the close of the Report are given some detailed analyses of cereal grains in which sugar, starch, and the albuminoids soluble and insoluble in alcohol, are separately determined. Analyses are also given of the very various products obtained from wheat by roller-milling. The whole is a magnificent contribution to the history of cereals. We now know far more of the characteristics of cereals grown on the American continent than we do of those produced in the United Kingdom. When will an English Agricultural Department inaugurate a similar study?

As we have no space for the details of the results, it is perhaps hardly fair to criticise. We would merely remark that dextrin is not reckoned by the best modern chemists among the constituents of barley, or of other cereal grains that have been thoroughly investigated. The method used for determining starch is apparently one yielding too high results, while the "fibre" shown in the analyses is far below the total cellulose and incrusting matter really present. We call attention to these errors of method, as they are very generally met with, and it is high time that they were remedied. R. W.

Longmans' School Geography. By George G. Chisholm, M.A., B.Sc. (London: Longmans, Green, and Co., 1886.)

ONE point which the recent discussions with regard to geographical education in this country has brought out

beyond dispute is that our teachers have wretched text-books in geography, and Germany has been held up to us as the model to follow in this as in many other respects in regard to geographical teaching. The Germans (as Mr. Chisholm points out in his interesting preface) have had long experience in working out an advanced system of education; they know that a limited period must be turned to account for the thorough teaching of a great variety of subjects, and accordingly they have learned to distinguish between what is indispensable as a ground-work and what must be omitted. In this country the study of geography is mainly a work of memory—the names of towns, rivers, mountains, with their populations, lengths, and heights. This and similar details are precisely those on which the Germans lay least stress, and as Mr. Chisholm has "earnestly endeavoured to guide himself by German examples," he anticipates that his book will appear more remarkable for what it omits than what it contains. Stated in his own words his object has been, in the first place, to draw a mental picture of the different countries and regions of the world, giving due relief to what is most distinctive in each region, and, secondly, to give special prominence to the relation of cause and effect, so as to enable pupils to realise that in geography there is something to understand as well as to commit to memory, in other words, to make geography a mental discipline as well as a body of instruction. Of course there is important work for the memory in geography as in every other branch of education, and this the author recognises, and provides for in his tables and printing. He insists, too, on the vital necessity of maps, without which there can be no adequate knowledge of geography. A text-book is supplementary to an atlas, and does not supersede it. These are high ideals which Mr. Chisholm sets before him; let us see how he fulfils them.

The whole volume contains 320 pages. The first 60 are devoted to an introduction dealing with mathematical and physical geography, which, as explained in the preface, is designed primarily for teachers, and is not intended to form part of the course for the pupils until they have gone through the whole body of the book.

The introduction is followed by a description of continents and countries. Of the 260 pages which remain for this purpose, Europe fills 150 pages, Asia 45, Africa 16, and America 32. The proportions are based on the degree of knowledge which an educated English boy or man should have of the respective countries and continents. Some of the divisions are original. Thus English counties are divided into corn and grazing, the countries of Asia into monsoon and non-monsoon countries. We have specially examined the sections devoted to the countries of Eastern Asia, for the sins of ordinary British school geographies are more apparent here than elsewhere—the sins, namely, of stereotyped inaccuracy, and of strings of names and numbers. Mr. Chisholm has not a superfluous line in any of these sections, the information is of the latest kind, and all the knowledge that the average boy requires of the countries is put in a short space.

As an instance of the care with which the work is done it may be mentioned that the puzzling variations of some Japanese names (*e.g.* Fujinoyama, Fujisan) are given and explained. On the whole, we are convinced that there is at present no school geography in the English language more calculated to give adequate and intelligent instruction in that subject than this, and can therefore strongly recommend it to those teachers who have lamented the absence of a sound text-book. It is to be hoped that Mr. Chisholm may see his way to producing a smaller work about half the size and price of this book for lower classes.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Physiological Selection and the Origin of Species

As Mr. Romanes has referred to my article in the current number of the *Fortnightly Review*, and stated that he is prepared to answer what he terms "the very obvious exceptions" which I have taken to his theory, I shall be glad to be allowed to state, very briefly, what those exceptions are, and to give an illustration of one of the more important of them.

(1) Mr. Romanes makes a great deal of the alleged "inutility of specific characters," and founds upon it his extraordinary statement that, during his whole life, Darwin was mistaken in supposing his theory to be "a theory of the origin of species," and that all Darwinians who have believed it to be so have blindly fallen into the same error. I allege, on the contrary, that there is no proof worthy of the name that specific characters are frequently useless, and I adduce a considerable series of facts tending to prove their general utility.

(2) In support of his view as to the swamping effects of inter-crossing, Mr. Romanes objects to the assumption of Darwin, "that the same variation occurs simultaneously in a number of individuals," adding: "Of course, if this assumption were granted, there would be an end of the present difficulty"; and his whole argument on this branch of the question rests on the assumption being false. I adduce evidence—copious evidence—that the supposed assumption represents a fact, which is now one of the best-established facts of natural history.

(3) Mr. Romanes states, as the special feature of his physiological varieties, that "they cannot escape the preserving agency of physiological selection." He gives no particle of proof of this, while I show that, on the contrary, it is hardly possible for them to survive to a second or third generation. It is on this point that I wish to give an illustration. Mr. Romanes speaks of his supposed variations as "showing some degree of sterility with the parent form," while continuing to be fertile "within the limits of the varietal form"; but I hold that any such variety (beyond single individuals) can hardly exist, while he has adduced no proof whatever of their existence. To show the improbability of their existence, let us suppose a definite case.

In a given species there is born an individual, A, which is infertile with the bulk of the species, but fertile with some few individuals of the opposite sex, *a*, *b*, *c*. Let there be a second individual, E, born from other parents in another part of the area occupied by the species, and fertile only with *e*, *f*, *g*. Other individuals, K, P, R, &c., may have similar relations, each infertile with the bulk of the species, fertile only with a few individuals which may be termed their physiological complements. Now each of these, separately, is a physiological variety, but the whole set, A, E, K, P, R, do not form one, but five distinct varieties. To form one variety all of them must be fertile with the same identical set of individuals of the opposite sex, and this seems to me to be so highly improbable that it must not be assumed till rigidly proved. Yet there is not one passage in Mr. Romanes' paper to show that he recognised this difficulty; on the contrary, he always speaks as if any number of separate physiological variations within one species must necessarily form one variety. It will easily be seen that the chances against any single variety of this nature being preserved are overwhelmingly great. For, first, at least two of the complementary individuals must survive to the breeding-season, and the chances against this are measured by the fertility of the species. If it produces ten young each year, the chances are between nine and ten to one against any one of them surviving. The chances against the *two* complements surviving will be about ninety to one; and then there remains the chances against the two meeting at the breeding-season, for, by the assumption, there is nothing whatever to bring them together but chance, and this may be any number of thousands to one.

There are, no doubt, other possible cases in which the physiological variety might be continued, but, as I have shown in my

paper, the chances against it are always very great. Here, then, are three objections to Mr. Romanes' theory which seem to me to be weighty and fundamental; yet he says, in effect, that he anticipated, and is prepared to answer, them. This, I must say, puzzles me; because in the whole of his lengthy paper, occupying seventy-five pages, I cannot find any adequate recognition of their existence, or any attempt whatever to answer them.

My apology for writing this is that I am shortly leaving England, and wish the readers of NATURE, who may not have seen the *Fortnightly*, to be aware of the character of the objections which Mr. Romanes declares that he anticipated, but apparently thought of too little importance to require any discussion in his paper. ALFRED R. WALLACE

I AM sorry that I have not succeeded in making my meaning clear to Mr. Romanes. I had hoped that my former letter (NATURE, September 2, p. 407) would have given some indication as to my father's views. With regard to the sentence quoted from the "Origin of Species," our views seem to differ so much that it seems useless to prolong the discussion.

FRANCIS DARWIN

Golf Club, Felixstowe, September 13

I HAVE read the numerous notes and letters in recent numbers of NATURE upon the origin of species and varieties with great interest. It seems to me that all your correspondents are raising an imaginary difficulty.

"If it is to the advantage of some particular variety not to resemble the parent form," then that variation must have been produced by some efficient cause acting upon the parent form alone. Is it not obvious that that cause still acting will be still more potent in producing that particular variation when the parent form intercrosses with the variety? This is, of course, supposing that the new variety is suitable to its environment; if it is not so, no amount of "propping up," whether by "amixia" or otherwise, would perpetuate it.

If, as is probably the fact, varieties or incipient species have arisen from individual divergences, amixia would tend to immediately suppress them in the case of animals and diœcious plants, as a new generation could not possibly arise without intercrossing with the parent stock. J. H. A. JENNER

4, East Street, Lewes

I SHOULD be glad to call Mr. Romanes' attention to a letter by Mr. Edmund Catchpool, published in NATURE, November 6, 1884 (vol. xxxi. p. 4), where he will find his theory of physiological selection very clearly put forward.

FRANK EVERSHED

113, Darenth Road, Stamford Hill, N.

Solution Discussion at the British Association

IT was a pity there was no discussion on solution in British Association, Section B, on Thursday last. More than the whole day was taken up with reading a great many papers, some of them having very little to do with the subject, so no time was left for discussion. I was indeed, by the courtesy of the Vice-President and the patience of the few remaining listeners, allowed to make a few remarks, but of course it was only possible for me to indicate that I had something to say.

In the papers referred to a good deal was said of solution being due to purely physical causes. Now this is either a truism or a veil to hide ignorance, and I am sure no one was a bit the wiser. What we want to get at is THE physical cause of solution. Again, a great deal was made of the part of the heat of solution that might be accounted for by the contraction in volume of the solution. This looks very learned and scientific, and no doubt is interesting from some points of view, but even if all the heat could thus be accounted for, it would not advance our knowledge of the cause of solution; it is merely surrounding the subject with cobwebs. The question would still remain, What is THE physical cause of this contraction?, and I maintain it is due to the affinity of all the elements for one another acting as pointed out in my papers on chemical affinity and solution published in NATURE, April 29 and July 22 of this year. The truth is, chemists, for convenience of study, drew a circle and called all within this "chemical affinity," and then forgot that the circle was their own making, and imagined it was Nature's work. This restriction has served its day, and must now be obliterated if we would understand the plainest teaching of the laboratory and make continued progress.

Portobello, September 9 WM. DURHAM

Actinotrocha of the British Coasts

IN NATURE of August 19 (p. 361), which I have only seen to-day, my friend, Mr. J. T. Cunningham, records as a novelty the finding in 1883 of *Actinotrocha* off Cromarty Firth. Without giving an exhaustive note of its occurrence off our shores since the discovery in 1856 of *Phoronis* by the late able and accomplished Dr. Strethill Wright, viz. one species from Ilfracombe, and another on an oyster-shell from the neighbourhood of Inchkeith in the Firth of Forth, the following remarks may be of interest. So long ago as 1858 the late Dr. Spencer Cobbold found *Actinotrocha* near Portobello, as was likely after Dr. Wright's discovery, and I have also since met with it in and off the Forth. Moreover, at the meeting of the Microscopical Society at which Dr. Cobbold read his paper, the lamented Dr. Carpenter mentioned that he had found *Actinotrocha* in abundance off the Island of Arran, probably when working at *Tomopteris* and other surface-forms with his friend, the enthusiastic E. Claparède, of Geneva. Besides these localities, Prof. Kolliker ("Kurzer Bericht an der westküste von Schottland," *Zeitsch. f. w. Zool.*, Bd. v. 1864) describes the occurrence of a *Phoronis* apparently identical with Dr. Wright's *P. hippocrepia* from Millport on the larger Cumbrae in the Clyde, a region in which the steam-yacht *Medusa* from Granton has lately been at work. It is probable, indeed, that *Phoronis* and its larval form (*Actinotrocha*) are more generally distributed round our shores than the scanty notices of them would lead one to suppose. Old shells in and off the mouth of the Forth, off the western shores, and these and other structures in the littoral region on the southern coast of England, as well as the shores of the Channel Islands, will probably produce many examples of *Phoronis*, while the careful scrutiny of the contents of the tow-net in similar localities will yield corresponding results as regards *Actinotrocha*. W. C. MCINTOSH

St. Andrews Marine Laboratory, August 25

The Manatee

I NOTICE in the review of Dr. C. Hartlaub's work on the Manatees, which appears in your issue of July 8 (p. 214), that the geographical range ascribed to that animal on the West Coast of Africa has its southern limit at the Quanza. A reference to earlier writers would, I think, justify us in believing that the manatee was once to be found as far south as the Cape of Good Hope, or else that it has been confounded with the hippopotamus.

Dapper, in his description of the Cape Settlement, speaks both of sea-cows—"zee-koeien of zee duivels, zoo groot als koeien, die bij wijlen te lande gaen weiden"—and of sea-horses—"zee-paerden, een zeer groot en wonderijgelyk zee-gedrocht" ("Naukenge Besch ijonige der Afrikaensche gewesten," p. 266; Amsterdam, 1676).

Here the hippopotamus is evidently the *zee-koe* or sea-cow, which occasionally feeds on dry land. May not the *zee-gedrocht*, the sea-monster, have been the manatee?

For Valentyn, also writing of the Cape of Good Hope, refers very explicitly to the manatee:—

"Onder de zee dieren telt men de zee koejen, de hier zeer veel en ongemeen swaar vallen, alzoo men er zommige van 4 of 5000 ponden gezien heeft. In West Indien *noemt men dit dier Manati* bij de Indianen, en anderen noemen het wel een Lamantine; hoewel er zijn die beide deze dieren nog eenigzins onderscheiden.

"Diergelijk zwaar zee paarden heeft men er ook, hoewel wat verder van de Kaap af, gezien. Zij vallen doorgans kastaniebruin" ("Beschrijving van Kaap de Goede Hoop," p. 115; Dordrecht and Amsterdam, 1726. Eighth volume of "Oud en Nieuw Oost Indien").

But here the manatee is called the sea-cow. What is the sea-horse (*zee-paarden*)? Can it be what Leguat saw at sea on his voyage from Amsterdam to the Cape—which he reached twelve days after the *rencontre?*

"Le premier jour de l'an 1691 nous eûmes le plaisir de voir assez distinctement une vache marine de couleur roussâtre (cf. the "kastaniebruin" of Valentyn) "qui faisoit voir la tete entière,

et quelquefois de la moitié du corps hors de l'eau. Elle était ronde et épaisse et paraissoit plus massive que nos plus grandes vaches. . . . Un de nos matelots nous assura que ces animaux avoient les pieds, comme vous pouvez voir dans la figure que voici."

This figure, however, except for the toes, which resemble fins or webbed feet, is unmistakably the hippopotamus! (See "Voyage et Avantures de François Leguat," vol. i. p. 35; Londres, 1708.) Leguat did not apparently consider it a manatee, for on p. 93 he gives a full description, with plate, of the lamentin or manati, which "se trouve en grande abondance dans les mers de cette Isle" (Rodriguez). The skin is "noirâtre."

Père Tachard plainly calls the hippopotamus the *vache marine*—he is speaking of the Cape: "on voit dans les grandes Rivières un animal monstrieux, qu'on appelle Vache Marine, et qui égale le Rhinocéros en grandeur" ("Voyage de Siam," vol. i. p. 78; Amsterdam, 1688). The plate accompanying is the hippopotamus, and we know that the Dutch colonists have always called this pachyderm the "zee-koe."

Kolbe ("Caput bonae spei hodiernum," p. 167, Nürnberg, 1719) speaks of the "zee kuh," the "meer kuh," the "zee pferd," and the "kuh fisch," all of which he appears to consider different names for the hippopotamus, notwithstanding that "in dem Tartarisch meere grosse Kuh-Fische schwemmern, die grosser als unsere Kühe in Europa waren, aber weder Schuppen noch Hörner hatten." This must be the dugong, surely.

Bogaerts ("Asia," p. 105; Amsterdam, 1711) distinguishes between "zee-paarden" and "zee-koien."

Dampier's mention of the manatee is probably well known:—"While we lay here (Blewfield River, between the Nicaragua and Veragna Rivers) our Moskito men went in their canoa and struck us some manatee or sea cow. Besides this Blewfield River I have seen of the manatee in the Bay of Campeachy, on the coast of Bocca del Drago and Bocco del Toro, in the River of Darien, and among the South Keys or little Islands of Cuba. . . . I have seen them also at Mindanea, one of the Philippine Islands, and on the coast of New Holland." Then follows a full description (see Dampier's "Voyage Round the World," vol. i. p. 33 *et seq.*, also pp. 2, 9, 41, 381, 463, and 547; London, 1729). Dampier also points out that the so-called manatee of St. Helena is really a "sea-lion."

Cape Town, August 4 W. HAMMOND TOOKE

Time Reform in Japan

THE following communication may perhaps interest your readers.

On my return home from America and Europe, I presented a report on the resolutions of the International Meridian and Time Congress, held at Washington last year, to which I was sent as a delegate. A Committee was appointed to discuss the matter contained in my report, and reported favourably. The following decree was issued on July 12, 1886, under the Imperial seal:—

(1) The meridian passing through the centre of the transit instrument at the Observatory of Greenwich shall be the initial meridian for longitude.

(2) Longitude shall be counted from this initial meridian in two directions up to 180°, east longitude being + and west longitude - .

(3) On and after the first day of the first month of the twenty-first year of Meiji (January 1, 1888), the time of the meridian of 135° E. shall be used as the standard time throughout the empire. D. KIKUCHI

Tremblement de Terre du 5 Septembre

L'ÉBRANLEMENT des couches terrestres, qui peut être considéré comme la suite du tremblement de terre du 27 août, a eu son centre dans le Piémont, dans les environs de Suse, au pied du Mont-Cenis. Le phénomène a été composé des secousses suivantes, qui ont toutes été tres-faibles dans la Suisse.

Secousses préparatoires. 4 septembre, 11h. 35m. soir (heure de Berne) Colombier (Neuchâtel); 5 septembre, 8h. 16m. soir, Briançon (Hautes-Alpes, France).

Grande secousse. 5 septembre, 8h. 55m. soir. Nous en avons des observations de Bienne, Berne, Lausanne, Morges, Genève, Vevey, Aigle, Villars-sur-Ollon, Bex, Monthey, Troistorrents, Sion, Savièse.

Secousses consécutives. 5 septembre, 11h. 55m. soir, Genève; 6 septembre, 4h. 10m. matin, Monthey (Valais); 7 septembre, 0h. 43m. matin, Genève. F.-A. FOREL

Morges, 12 septembre

Lunar Rainbow

A BEAUTIFUL lunar rainbow was plainly visible here for a few moments last evening. The eastern sky being clear, the moon looked fully out from behind dark clouds in the west at a moment when rain was falling lightly. Turning quickly away from her light, in the hope of seeing a bow, I was not disappointed. A semicircle of pale, whitish light, was projected against the eastern sky, much smaller in diameter, apparently, than a sun-bow, and without any traces of colour.

Reflecting on the circumstance that repeated efforts have never, previously, enabled me to see a lunar bow, although the conditions necessary for its formation are common enough, I am tempted to think that the phenomenon can only be seen when the atmosphere is unusually clear. The light issuing from the bow is so faint that the slightest mistiness of the air intervening between itself and the spectator is probably sufficient to, practically, extinguish it. Last night the air here and over the Channel was extraordinarily pellucid, lights on the French coast which are hardly ever seen being plainly visible, while others, nearer neighbours, flashed with most unusual brilliancy.

Aurora

THE aurora seen in Ireland on July 27, and described in NATURE, August 5, p. 312, was visible in this vicinity. It was the finest observed thus far this year, with the exception of that of May 8. Other dates on which the aurora has been seen in this locality recently are as follows: June 29, June 4, and April 14. It has been noted that these appearances of the aurora have been coincident with the return of the disturbed area on one side of the sun (see NATURE, July 22, p. 278), and likewise with widespread and violent storms.

THE SOLAR ECLIPSE OF AUGUST 29

THE following communication, dated Grenada, September 5, is published by the *Times* from its correspondent with the Eclipse Expedition. It should be compared with the communication made by Prof. MacAlister to Section A at the Birmingham meeting of the British Association (NATURE, September 9, p. 441), and with the article in the same number (p. 437), describing the arrangements for observation.

"The observations of the corona during the last two eclipses, including that observed in Egypt, have been confirmed by the present. Capt. Darwin's observations with the coronagraph seem disappointing, the glare of irradiation from the body of the sun, and not the true corona, being visible on his plates. The bright lines seen in the spectra of the prominences are displaced in such a direction as to prove that there is in them a downrush of gas towards the sun.

"The curious prolongation of the corona observed on several previous occasions to occupy the sun's equatorial plane, does not appear in any of the photographs taken, though it was visible at all the stations except Mr. Lockyer's."

PHOTOGRAPHY OF THE SOLAR CORONA

UNDER the above title we have received the following communication with reference to the results of the recent eclipse observations:—

Accounts have appeared in your journal of my attempts to photograph the corona of the sun without an eclipse. Many of the plates obtained presented appearances which seemed not to myself only, but to several scientific men who must certainly be con-

sidered to be amongst those who are exceptionally competent to give an opinion on this point, to be most probably due to the corona. Plates taken in England about the time of the eclipse of May 6, 1883, and drawn by Mr. Wesley before any information reached this country of the observations of the eclipse, presented not only a general resemblance to those taken during the eclipse, but showed the remarkably-formed rift on the east of the sun's north pole which is the main feature of the corona, as photographed at Caroline Island. It is true that since the summer of 1883 I have not been able to obtain in England photographs which show satisfactory indications of the corona; but the abnormally large amount of air-glare from finely-divided matter of some sort, which has been present in the higher regions of the air since the autumn of 1883, might well be considered a sufficient cause of the want of success. This well-known state of the sky rendered the plates taken by Mr. Ray Woods in Switzerland in the summer of 1884 inconclusive as to the success of the method. During the past year photographs of the sun have been taken at the Cape of Good Hope, and are under discussion by Dr. Gill.

Such was the state of things before the eclipse of August 29. The partial phases of this eclipse furnished conditions which would put the success of the method beyond doubt if the plates showed the corona cut off partially by the moon during its approach to and passage over the sun. As the telegrams received from Grenada and a telegram I have this day received from Dr. Gill at the Cape of Good Hope state that this partial cutting off of the corona by the moon is not shown upon the plates, I wish to be the first to make known this untoward result. I regret greatly that a method which seemed to promise so much new knowledge of the corona, which under ordinary circumstances of observation shows itself only during total eclipses, would seem to have failed. At the same time, I am not able to offer any sufficient explanation of the early favourable results to which I have referred briefly in the opening sentences of this letter.

WILLIAM HUGGINS

Upper Tulse Hill, S.W., September 11

In reply to a similar communication which appeared in the *Times*, Mr. A. A. Common writes to that journal as follows:—

"Dr. Huggins, in his letter in to-day's issue, seems to consider that the failure to get a picture of the moon projected on the corona of the sun during the partial phases of the last eclipse is fatal to his method of photographing the corona; but it is quite possible, and, indeed, probable, that this is due entirely to the state of the sky, for against such unfavourable negative as this we have the positive evidence that the moon has been seen so projected in various solar eclipses, and in one case it has been so photographed. This was by Liais, at Paranagua, in 1858, under conditions that were not, as far as concerns the processes employed, nearly so favourable as those now in use. This single piece of positive evidence, if correct, is of vital importance in showing that the present failure is probably due only to such temporary causes as have prevented Dr. Huggins getting lately such promising plates as those he obtained in 1883.

"Ealing, September 13 "A. A. COMMON"

THE RECENT AMERICAN EARTHQUAKE[1]

THE author gave a brief account of the earthquakes in Eastern Europe of August 27, which seem to have travelled eastwards from Malta to the south of Italy. It is a curious coincidence that the first important indications of earthquake disturbance in the United States took place on that date, when the geyser of the Yellowstone spouted forth and when the first moderately severe shock at Charleston occurred. The principal shock was on Tuesday night, August 31. This is the one which has done most damage, and which was felt over a wider area than any previously recorded in North America. It has, however, been succeeded by shocks, fortunately of less intensity, which have been felt over a still wider area. The later shocks of Thursday and Friday were felt in Nevada and California.

The author gave a description of the earthquake, founded upon the newspaper telegrams and upon a telegraphic despatch which Major Powell had kindly forwarded at the author's request. The latter is as follows:—

"The earthquake is the most severe on record in the United States, and affected the greatest area. Origin along line of post-Quaternary dislocation on the eastern flanks of the Appalachian, especially where it crosses central North Carolina. There were slight premonitory shocks in the Carolinas for several days, moderately severe shocks occurring near Charleston on August 27 and 28. The principal shock, causing great destruction in Charleston, originated in central North Carolina on August 31, 7.50 p.m., 75th meridian time. Thence the shocks spread with great rapidity in all directions, with velocity varying from 25 to 65 miles a minute, over an area of 900,000 square miles, or one quarter of the United States—from the Gulf of Mexico to the Great Lakes and Southern New England, and from the Atlantic seaboard to the Central Mississippi Valley. In the Carolinas it was accompanied by landslides, crevasses, and great destruction of property. Half of Charleston is in ruins; about 40 lives were lost. No sea-wave has yet been reported. A second moderately severe shock occurred at Charleston at 8.25 a.m. September 1. Minor shocks followed at increasing intervals. The principal shock was felt over this vast area in intervals of 15 minutes, and recorded at some principal points on a scale of intensity of 5 as follows:—Raleigh, 4, 9.50 p.m.; Charleston, 5, 9.54; Cedar Keys, Florida, 2, 10.05; Knoxville, 3, 9.55; Memphis, 4, 9.55; St. Louis, 1.2, 10.00; Milwaukee, 3, 10.06; Pittsburg, 4, 10.00; Albany, 2, 10.00; Springfield, Mass., 1, 10.00; New York, 2, 9.53."

Prof. Carvill Lewis has studied a previous earthquake in the North-Eastern States. This ranged along the north-eastern flanks of the Appalachian Chain. The author described the structure of Eastern North America, and the lines of old earth-movements therein to which both earthquakes seem to be related.

The local phenomena of the recent earthquake may be summarised as follows:—Fissures were formed, some running north to south, some east to west, out of which mud and sand were ejected. Several telegrams speak of stones falling from the air, which (if true) must previously have been ejected from such fissures. No tidal wave has been recorded, nor has any alteration of level of land or depth of sea occurred, although the earthquake was noticed at sea off Charleston; but some passing disturbance of the water seems to have occurred at Sullivan's Island near Charleston, for the high water spoken of could not be a spring tide, as the tides then were the neap tides. The accounts agree in the earthquake being accompanied by rumbling noises. Accounts differ as to the direction of the vibratory movement, but it was probably from the south or south-south-west to north or north-north-east, both at Charleston and New York. As usual in earthquakes, wells and springs have been affected; some dried up, whilst water has appeared where before there was none. The natural gas wells of Pennsylvania have been affected, and the supply much diminished. Perhaps the most interesting phenomenon is the

[1] "Notes on the Recent Earthquake in the United States; including a Telegraphic Despatch from Major Powell, Director of the United States Geological Survey." Read at the British Association by W. Topley, F.G.S., Geological Survey of England, President of the Geologists' Association.

outburst in the Yellowstone Park of a geyser which has been quiescent for four years.

All the evidence so far published tends to show that the earthquake was a true seismic disturbance, which was probably transmitted along certain lines of great rock-masses, or along lines of weakness; but details to enable us to determine these points are not yet to hand.

DR. KLEIN'S REPORT ON MILK SCARLATINA

In a recent Report to the Local Government Board, "On Certain Observed Relations between Scarlatina in various Districts of London and Milk supplied from a Dairy Farm at Hendon," Mr. Power has related the circumstances (NATURE, vol. xxxiv. p. 393) under which I became associated in inquiry at the farm in question; and, while briefly indicating certain provisional inferences of my own as to the nature of the malady discovered among the cows there, Mr. Power goes on to promise an account by me of the special features and pathology of the disease. This I now proceed to give.

The cows (I. and II.) which were the first subjects of my investigations had on the teats and udder several flat irregular ulcers, varying in diameter from $\frac{1}{4}$ to $\frac{3}{4}$ of an inch; some ulcers were more or less circular, others extended in a longitudinal direction on the teat. The ulcers were covered with a brownish or reddish-brown scab, which, when scraped away, left exposed a granulating slightly indurated base. The margin of such ulcer was not raised, nor was there any perceptible redness of the skin around. But where I afterwards got the opportunity of watching the earlier stages (especially in animal IV.) it was noticed that a small vesicle made its appearance on a greatly swollen and red teat, in the course of a couple of days assuming the character of the above ulcers. In another cow, an ulcer about $\frac{1}{2}$ inch in diameter, was becoming covered in its central part with a scab, while at its margin vesiculation was still distinctly visible.

As a rule, *i.e.* in most animals, the disease affected the teats, but in some there was also on the lower part of the udder here and there an ulcer. In such animals, patches denuded of hair were noticed on various parts of the skin, the tail and back particularly. In these patches the epidermis was scaly, and the cutis more or less thickened. The animals looked thin, but not strikingly so, except in one or two cases of animals that had only a few weeks ago been admitted to the place, and which therefore had calved comparatively recently (see Mr. Power's Report). As regards the feeding capacity of affected animals, their milking power, and their body temperature, nothing abnormal could be detected.

Two animals (to be referred to as cow III. and cow IV.) became the special subjects of study after they had been removed from the farm to the stables of the Brown Institution.

The temperatures (Centigrade degrees) of cow III. were as follows:—

	Morning temperature	Evening temperature
January 4	38°·8 ...	38°·7
„ 5	38·9 ...	38·9
„ 6	38·8 ...	38·3
„ 7	38·9 ...	—
„ 8	39 ...	39
„ 9	38·8 ...	38·7

The temperature afterwards remained as above without alteration.

The temperatures of cow IV. were:—

January 6	38°·4 ...	38°·3
„ 7	38·7 ...	—
„ 8	38·4 ...	38·8
„ 9	38·6 ...	38·5

In animal III. the ulcers were present, and on January 4 were at their full development and covered with crusts. They gradually died away, and subsequently healed up by January 10, leaving, however, a whitish indistinct flat scar.

When this animal was received there were noticed on its coat several patches where the hair was gone, and the epidermis was rough and scaly.

Animal IV. when received showed several scabs in the skin of the back; it had also muco-sanguineous discharge from the vagina (the animal was in the third month of pregnancy) and redness and excoriation of the mucous membrane of the vagina. One teat, which was much swollen and inflamed, presented in several places brownish crusts. These when taken off left an infiltrated firm sore, from which, when squeezed, a thickish lymph oozed out. Similar crusts were found on other teats and on the udder. The greatest development of the sores in this cow was on January 7. On January 9 the sores were decreasing; the animal was then killed.

On opening the chest it was found that both lungs exhibited in the upper posterior lobes numerous petechiæ under the pulmonary pleura, the peripheral lobules of these parts being much congested. There were numerous adhesions by recent soft lymph between the lower lobes of the lung and the costal pleura, particularly laterally. In the liver there were several reddish streaks and patches, reaching from the surface of the organ to a depth of about a quarter of an inch. In these patches the liver tissue was much softened. The spleen and kidneys, with exception of slight congestion, appeared normal. In the placenta there were numerous petechiæ.

Cow III. was killed on March 12. For some days previously the animal had been getting very thin, notwithstanding its ravenous and excessive eating. On post-mortem examination the following appearances were found:—

In the lungs there were numerous lobules, especially in the peripheral parts, which showed great congestion; there were in addition pleural adhesions; the cortex of the kidney was congested, but its medulla was pale.

Experiments were now made with the matter of the ulcers, with a view of ascertaining whether or not the disease was transmissible to other animals.

On January 7, when the ulcers of cow IV. had reached their maximum development, I took scrapings from some of the ulcers on the udder and teats, having first removed the crust, and inoculated in several places the skin of groin and inside of ear of two calves (1 and 2). For inoculation a superficial small incision (not longer than about a quarter of an inch) was made, passing in an oblique direction through the superficial part of the corium, and into this pouch a particle of the scraping was rubbed.

On January 9, with scraping of ulcers of the cow before she was killed, I inoculated two calves (3, 4), introducing the matter as before into the corium of the groin and of the inside of ear.

Calves 1 and 2 showed during the first three days after insertion of the matter no change at the seat of inoculation.

Four days after inoculation:—There was in calf 1 one place in the groin which promised to become an ulcer. Calf 2 showed on the ear one promising place, the other places of inoculation having nearly healed.—At the same distance of time after inoculation calf 3 showed two promising places on the ear, and calf 4 showed two promising places in both groin and ear. Calf 3 also showed a kind of vesiculation at the margin of the spot inoculated and commencing formation of a crust in the centre. What I call promising places of inoculation were spots that had become swollen and tender, the other and not promising places were spots that seemed healing or were already healed and dry.

On the sixth day:—Calf 1 showed four successful places in the groin; the places had become swollen and enlarged with imperfect vesiculation at the margin and formation of crust in the centre. Calf 3 had four successful places on the ear, and calf 4 had the same number in the groin.

On the seventh day:—In calf 1 all places except one in the groin had nearly disappeared. This place was now a distinct ulcer covered with a crust, on removing which a granulating infiltrated base was exposed. In calf 2 all places of inoculation were decreasing, covered with small scabs, easily detached. In calf 3 the sores on the ear had enlarged to about half an inch in breadth, each of them covered in their whole extent by a brownish crust. In calf 4 all except one place on ear were healing.

On the eleventh day:—Calf 1 had still one ulcer in groin not yet healing. Calf 2 had one ulcer on ear not quite healed up. Calf 3 had four big ulcers still progressing; crusts thick, and corium much indurated. Calf 4 had one ulcer on ear much diminished in size.

By the eighteenth day:—The ulcerations in calf 3 (one ulcer had been cut out for microscopic examination) had all healed up and become converted into flat scars. In the other animals the healing was completed at an earlier date.

Simultaneously with the above experiments several inoculations with materials of the ulcer of cow No. IV. had been made into the skin of the groin of ten guinea-pigs and of three dogs. In the guinea-pigs no result was obtained; but in one of the dogs one place of inoculation appeared swollen and inflamed on the third day. On the fifth day this place was an oblong ulcer of about a quarter of an inch in diameter; the margin was red and swollen, but the centre was without crust (the animal had been frequently seen to lick it). On the seventh day the ulcer was much smaller, and it had nearly healed up by the tenth day.

From these experiments there can be no doubt whatever that by inoculating a particle of matter from the sores of an affected cow a positive result has been obtained in all four calves. In calf 3 this result was best and most striking. After an incubation of about three days the places of inoculation became swollen, tender, and spreading; on the fifth to the sixth day the change was distinct, the successful places having become sores; in the marginal part showing vesiculation, and in the centre formation of crusts. The sore enlarged during the next few days, and on removing the crust a raw surface was exposed, the corium itself being found infiltrated. According to the intensity of the process the retrogressive change sets in later or sooner; in slight cases the healing begins about the ninth or tenth day, in severe cases (calf 3) not before the end of the second week.

Having thus demonstrated this disease of the cow to be directly communicable from animal to animal, I set to work to study its minute anatomy.

The microscopic examination of fine sections through the ulcer of the cow shows the following conditions:—

The corium throughout the whole extent of the ulcer is infiltrated with round cells. This infiltration, though densest in the central portions of the ulcer, is sufficiently pronounced even in the peripheral parts, but it gradually fades away on passing from the ulcer to the normal skin. The infiltration in the deeper parts of the corium is limited to the vascular branches, but in the superficial parts is more diffuse, the papillæ becoming at the same time thicker. This thickening of the papillæ fades off towards the periphery of the ulcer. The most noteworthy changes are, however, present in the epithelium. In the peripheral portions of the diseased part there are present in the superficial layers of the stratum Malpighii close to the stratum lucidum, as also in the stratum lucidum itself, numerous cavities of different sizes. These cavities lie closely side by side; the most superficial ones are either covered by the stratum lucidum or extend between the layers of this stratum. The former cavities descend into the depth of the epithelium; at the very margin of the diseased part they are smallest, and they do not in depth comprise more than the superficial third of the stratum Malpighii. They enlarge in depth gradually as we pass from the periphery of the ulcer towards its centre; at its very centre they involve the whole thickness of the stratum Malpighii. At the same time it is to be noticed that, at the marginal parts, the cavities, although closely placed side by side, are well separated from one another by thicker or thinner trabeculæ composed of epithelium; while at or near the centre the ulcer these trabeculæ get destroyed, and the cavities become confluent, and the covering layers of the cuticle having here also given way, their contents extend on to the free surface of the ulcer. These contents, which go to form what has been above mentioned as the crust, spread thus gradually over the surface, not only of the centre, where the stratum lucidum has become lost, but also over the rest of the ulcer. In the marginal positions, *i.e.* where the superficial layers of the cuticle are still present as cover of the above cavities, this layer (*i.e.* the stratum lucidum) separates the contents of the cavities from the crust. The contents of these cavities consist (*a*) of an albuminous fluid looking, in hardened sections, uniformly granular or containing also fibrinous threads; (*b*) of a few red blood corpuscles; and (*c*) chiefly of round cells or pus cells, the nuclei of which, near to and on the surface, gradually break up into amorphous granular matter.

In the central parts of the ulcer the whole exudation undergoes degeneration into debris, and not only in its superficial, but also in its deeper portions. While some cavities contain very few cells and are filled chiefly with albuminous fluid (granular or fibrinous), others are almost entirely filled with pus cells closely packed together. In the papillæ near the cavities the blood-vessels are engorged and there is also escape of red blood disks.

On a careful examination it is evident that the origin of these cavities is in enlargement of and exudation into the tissue of the papillæ, but only of those portions nearest to the stratum lucidum, and from hence arises formation of cavities in the cuticle. The whole anatomical details of the distribution and arrangement of these cavities recall vividly the conditions observed in the vesicles of cow pock and of sheep pock, and on comparing under a low power of the microscope a section through a sheep pock with a section through the ulcer of the cow now under consideration, the similarity is very striking indeed.

There are, however, anatomical differences between the two diseases. The infiltration of the corium is slighter in the cow ulcer than in the sheep pock, and in the cow ulcer the cavities form in a more superficial stratum of the epidermis.

There is in the disease we are now considering a good deal of infiltration of the epithelium by round cells derived from the cavities, not only into the stratum Malpighii, but also, and particularly in the marginal parts, into the cuticle; the round cells burrowing in great numbers between the scales of this stratum, and ultimately reaching the free surface to join those of the crust.

Fine sections made through the ulcer artificially induced by inoculation in the ear of calf 3, proved its complete identity in anatomical respects with the ulcer in the cow. The infiltration of the superficial corium; the formation of cavities, filled with exudation cells and fluid, in the superficial layers of the epithelium, particularly between the layers of the cuticle; the final destruction in the centre of the ulcer of the covering cuticle; and the extension of the exudation over the free surface to form here the crust, are the same in both instances.

Microscopic examination of the internal organs of cow IV. revealed facts as follows:—

In the lung.—Sections made through the portions above mentioned as containing much congested lobules, show not only great congestion of the blood vessels, large and small, but a large amount of hæmorrhage; blood in substance being present in the air vesicles and infundibula, in the lymph spaces of the interlobular septa, and in the tissue and lymphatics of the pleura. In the latter membrane numerous diplococci are to be met with. Here and there the same diplococci occur in the alveolar wall and in the tissue of the interlobular septa.

Sections through *the liver* show a great deal of change. Under the capsule, as well as in the substance of the liver, there occur, in connection with the interlobular branches of the portal vein, larger and smaller foci of inflammation, consisting in the presence of numerous round cells. Some of these foci are several millimetres in diameter, others are very small. From the interlobular tissue the inflammation extends into the lobules between the liver cells. The liver cells of these lobules involved in the inflammatory process are swollen up, and many of them are undergoing disintegration. In some of these foci, particularly those situated in the vicinity of the capsule, the round cells are so much crowded that given foci look almost like miliary abscesses. The blood vessels are much distended and filled with blood.

Numerous diplococci and short coccus chains occur in the parts surrounding the inflammatory foci. These are particularly numerous near the capsule in the vicinity of inflamed parts.

Sections through the *kidney* showed well-marked glomerulonephritis; infiltration of the sheath of the cortical arterioles with numerous round cells; the epithelium of the convoluted tubules swollen, opaque, and in many places disintegrating.

The lungs and kidney of cow III. showed on microscopic examination the same appearance as in cow IV.; in addition there was a good deal of round-cell infiltration in the wall of the infundibula and bronchi in the lung, and around the cortical arterioles in the kidney. In the blood-clots filling the alveoli and small bronchi of the lung there were present larger and smaller clumps of micrococci.

Search was now made for micro-organisms inhabiting the tissues of the ulcer of the cow, with a view of ascertaining what were present, and afterwards whether any single kind of those found had the power, when dissociated from the diseased tissues and inoculated into healthy animals, of transferring the disease.

Removing the crust, scraping off the most superficial layer, then squeezing the ulcer so as to collect a droplet of lymph, I spread it in thin films on cover-glasses, and dried, stained, and mounted the several specimens in the usual manner. Such a specimen, examined under the microscope, revealed a number of red blood disks, mixed up with large numbers of pus cells, each of which contained two, three, or four small nuclei and remnants of epi-

thelial cells. Amongst the pus cells numerous dumb-bells of micrococci (or diplococci), and a few short chains of the same, were met with. In size these micro-organisms do not differ from those described in connection with foot-and-mouth disease. In many sections—stained in fuchsin, or in methyl blue, or in gentian violet—through the diseased tissue of the cow, as well as that of calf 3, there were found the same diplococci and chains in the contents of the superficial cavities, as well as in the depth of the epithelium. In the latter stratum they were met with abundantly throughout the whole extent of the marginal portion of the ulcer, but not beyond it. In the superficial parts, namely, in the contents of the cavities in the stratum lucidum, the same chains were to be found, provided the pus cells were not too closely packed. They were very numerous in the tissue of the crust, and also in the superficial central portions of the ulcer that had undergone degenerate change. There occurred also in the crust and in the necrotic parts of the ulcer numerous clumps of zooglea of micrococci; but these micrococci are not to be confounded with the chains of streptococci to be presently described, nor yet with those streptococci which are found occurring singly.

From the deeper parts of an ulcer of cow IV. material was obtained with which tubes containing either solid nutritive gelatine, or Agar-Agar mixture, were inoculated. After some days, and in both media, a micrococcus appeared, the growth of which was extremely characteristic. These are its characteristics, in the nutritive gelatine: after 3 to 6 days' incubation at 20° C., the growth made its appearance at the point or line of inoculation, in the form of small points or granules, whitish in colour and tolerably closely placed. During the next few days their number and size increased. At the end of a fortnight the line of inoculation was visible as a streak of whitish granules or droplets, some large, others small, more or less closely placed. On the surface of the gelatine the growth, like a film of granules, spreads slowly in breadth, but even after months remains small. When inoculated into the depth of the gelatine, the channel of inoculation becomes visible as a whitish streak, made up of smaller and larger droplets. The gelatine is not liquefied by the growth. The same characters are assumed by the growth in Agar-Agar mixture and in solid serum. The general aspect of the growth in gelatine, in Agar-Agar, and in serum, is very similar to that presented by the *streptococcus* of foot and mouth disease (see my report of this year upon that malady [1]), but with this difference, namely, that in gelatine tubes the streptococcus of foot-and-mouth disease is a little faster in its growth, and its component granules are a little more distant. Nevertheless, I have tubes of both kinds of organisms in gelatine and in Agar-Agar—tubes which cannot be from their general appearance easily distinguished. In faintly alkaline broth, or in broth and peptone, the micrococcus of the cow ulcers grows readily, and in the same manner as that of foot-and-mouth disease. But there is one test by which the two kinds of organism can be very readily distinguished: the streptococcus of foot-and-mouth disease, when grown in milk, does not affect the fluid character of the milk, whereas milk inoculated with the organism obtained from the cow's ulcer will, if kept for two days in the incubator at 35° C., have been turned completely solid. This difference is a very striking difference, and a few days' growth in milk suffices for distinguishing without fail between the two.

The microscopic examination of a culture in broth peptone, in gelatine, or in Agar-Agar mixture shows that the growth consists of spherical micrococci, arranged as diplococci, and as shorter and longer straight, wavy, or curved chains—streptococcus,—these latter sometimes of great length. As regards the shape of the micrococci, the mode of their division, the branchings of the chains, the presence here and there in the chain of a large element amongst the smaller ones, the organisms of the ulcers hardly differ from the description which I am preparing of the streptococcus of foot-and-mouth disease. The elements of a coccus chain of the foot and-mouth micro-organism are, however, smaller than those of the disease under consideration.

The streptococcus chains of a growth in broth are short during the first few days; but later on, when the growth settles down more into the deeper parts of the broth, the chains become of great length. So also in Agar-Agar tubes of one to two or more weeks' incubation.

A curious fact, to which importance must provisionally attach, is this: In a cow having several of the ulcers on the teats, the fingers of the milker pressing over the ulcers would constantly rub off from the latter particles of matter, and the fingers and the teat being kept moist, this matter would easily mix with the milk as it passes from the teat. To learn whether the milk *while in the udder* contained the streptococci, the following experiment was made: A teat free of any ulcer was milked so as to obtain a few ounces of milk, and from this milk a large number of gelatine and Agar-Agar tubes were inoculated; a second teat of the same cow, affected by an extensive ulcer, was milked to the same extent, and from the milk thus obtained a large number of other gelatine and Agar-Agar tubes were inoculated. In the first series no single tube showed the growth of the above-described streptococcus, whereas in the second series one gelatine tube and one Agar-Agar tube were found to develop the typical growth of the streptococcus.

We cannot draw any certain inference from this one observation, but evidently the experiment deserves repetition.

With a cultivation (a third sub-culture, in Agar-Agar mixture of this streptococcus, I, on February 1, inoculated subcutaneously in the groin two calves (5 and 6) On February 27 calf 6 was found dead. The subcutaneous tissue at, and for some distance around, the seat of inoculation showed much effusion, and the inguinal glands were swollen and red. There was peritonitis, with sanguineous exudation, congestion, and hæmorrhagic spots in omentum and in the serous coat of the stomach. The spleen appeared small and its capsule thickened. The liver was greatly congested. Kidneys were large and much congested. The ileum was much congested in its mucous membrane, and the epithelium detached in flakes. The mesenteric glands belonging to the ileum were greatly enlarged and hyperæmic. Both lungs were congested, the superficial lobules showed so much congestion that they looked almost solid, and were of a deep red colour. A few petechiæ under the pleura. Bronchial glands enlarged and congested. There was pericarditis, and the heart was distended by, and filled with coagulated blood. The organs of the throat were found much congested. The hairy parts of the skin were not examined.

Calf 5 showed on March 7, around the nostrils and lips of the mouth, and on hard palate and gums, numerous irregularly outlined patches not raised above the level of the skin. These patches had a discoloured, brownish, very slightly raised margin, and a paler centre; they were round or irregular, some as small as $\frac{1}{8}$ of an inch, others four to six times larger. The animal was killed on March 8. On post-mortem examination the following appearances were noted: Congestion of some of the peripheral lobules in both lungs; the pleura pulmonalis slightly opaque, numerous soft lymph adhesions between it and the costal pleura; in the spleen several hæmorrhagic patches under the capsule in the shape of bullæ filled with semi-congealed blood; spleen pulp softened and very congested; kidney congested; organs of the throat congested.

There can then be no doubt that a definite disease has been produced in both animals, of which the affection of the lungs is a conspicuous feature, and coincides with, though more pronounced than, the lung disease noticed in cow IV.

In calf 5 there was, in addition, the disease of the skin and in the mouth, which, as the microscopic examination proved, is in a certain degree similar to the disease in cow IV. and calf 3. More in detail, this is what is found as regards the skin: The tissue of the papillæ and of the superficial corium is infiltrated with round cells, and the blood-vessels of the papillæ are distended and filled with blood. In their peripheral portions, their most superficial parts, the papillæ are very much distended by extravasated blood and round cells;—in fact the first rudiments of cavities are forming in them. The same condition, but more pronounced, obtains in the cuticle, where between its layers there are present small cavities filled with blood and round cells, or only fluid and a few round cells. There is, in addition to this, a general infiltration with round cells of the layers of the cuticle. The brownish-reddish colour of the marginal parts is due to this condition. In the central part the cuticle is loosened by the formation of such cavities containing fluid and a few round cells; by this its layers were separated and ultimately detached. In the cavities of the cuticle occur very fine diplococci and chains. So also in the infiltrated and enlarged papillæ, and in the deeper layers of the epithelium in the whole extent of the diseased skin, diplococci and short chains are present.

In neither of these cases of subcutaneous inoculation was there found any rent or breakage of the stratum Malpighii, *i.e.* no real ulcer. The anatomical features here described in many respects

[1] To appear in the Supplement to the fifteenth volume of the Board's Reports.—G. B.

resemble the lesion of the skin in human scarlatina (see my report for 1876). I did not, unfortunately, look at other (the hairy) parts of the skin to see whether there were any such patches in this calf. (Some observations on the kidney of calf 5 are noted in the sequel.)

Examination of the organs of calf 6:

(*a*) *The lung.*—Congestion of all blood vessels, large and small. Transudation of fluid and hæmorrhage into the alveolar cavities of part of some lobules of the lung, while the rest of the alveolar cavities are collapsed, the capillaries around them very much congested; infiltration with leucocytes of the interlobular septa, extending also into the inter-alveolar septa. In some of the lobules next to the pleura the engorgement of the capillaries is extremely great, blood *en masse* filling the alveoli to the extent of producing a state of red hepatisation. The pleura itself is thickened by exudation of fluid and leucocytes. The bronchi do not show any distinct alteration. Numerous diplococci and a few chains are met with in the pleura and in the congested parts of the lobules, in the alveolar wall, and in those alveolar cavities which contain exudation and blood. The bronchial glands show great changes: the capsule and septa being much thickened by exudation and leucocytes; the lymph vessels everywhere filled with round cells; the tissue of the follicles and medulla much swollen.

(*b*) *The liver* shows extreme congestion of all vessels in all parts, inter- and intralobular. The liver-cells are opaque, granular, and atrophic.

(*c*) *The ileum.*—The epithelium of the surface detached and gone; the epithelium of the Lieberkühn follicles loosened, and in most places detached; the mucosa shows great congestion and infiltration; in the superficial layers the villi show hæmorrhage, the tissue being filled with blood corpuscles, fibrin, and leucocytes; and in many spots the superficial layers of the mucosa are necrotic.

The Peyer's glands are much swollen and inflamed; the central portions of their follicles are breaking down.

Micrococci and bacilli pervade everywhere the tissue of the mucosa. The mesenteric glands in relation with the ileum have their capsules, septa, follicles, and medullary cylinders much congested and inflamed.

(*d*) *The kidney.*—The changes in this organ are highly interesting, since they completely coincide with those in acute scarlatina nephritis in man: great congestion of the cortex, leading in some parts to hæmorrhage into the parenchyma; glomerulo-nephritis with exudation of albuminous fluid and blood into the cavities of the Malpighian corpuscles; granular or opaque swelling of the epithelium of the uriniferous (convoluted) tubules, with degeneration into granular debris of many of the epithelial cells; miliary foci of aggregations of round cells around small bloodvessels; congestion of the medulla.

[The kidney of calf 5 was also examined microscopically, and the changes were exactly the same as those found in the kidney of calf 6, viz. congestion of the glomeruli, glomerulo-nephritis, transudation of albuminous fluid and red blood corpuscles into the cavity of Bowman's capsule; opaque swelling of the epithelium of the convoluted tubules; granular disintegration of the epithelium in many places; infiltration with round cells around some arterioles of the cortex; and congestion of the medulla.]

(*e*) *The heart's blood* was examined for organisms, and in it, by the staining with Weigert's gentian violet, a few diplococci and a few chains could be distinctly detected.

Cultivations were made with this blood in tubes containing Agar-Agar mixture, and a growth of the streptococcus was obtained in all respects identical with the streptococcus that had been employed for inoculation of this animal.

In view of the whole of this evidence, I consider it conclusively established that this streptococcus is identical with the virus of the cow disease.

We have, then, inoculated subcutaneously with sub-cultures of the streptococcus these two animals, calves 5 and 6, with the result of producing a general disease, which in many respects bears a close resemblance to human scarlatina. The minute anatomical characters of the eruption on the skin around the nostrils and mouth in calf 5 is of much significance in this connection, as also is the disease in the liver in both animals, and above all, the disease in the kidney. This latter organ corresponds so closely with a kidney of an acute case of human scarlatina that sections made of the one and compared with those of the other, of which I preserved a large collection from my former investigation into the anatomy of human scarlatina (see Medical Officer's Report for 1876), show no difference whatever.[1]

The outcome of the investigation thus far, and it is of importance until further differentiated observations shall have been made, may be stated thus:—By inoculating the virus directly taken from the local disease (the ulcer on the teats) of the cow into the corium of the calf the same local disease is produced, namely, a change in the skin, which commences as a congestion of the papillæ and corium, and an exudation of fluid and leucocytes. This leads, in the superficial parts of the epidermis, to the formation of cavities, which, enlarging, and extending, and opening on to the surface, and extending into the depth, ultimately lead to the formation of an ulcer. But the virus, in the form of an artificial cultivation of the streptococcus derived from the above ulcer of the cow, when inoculated into the subcutaneous tissue, that is, when introduced almost directly into the vascular system (for all matter injected subcutaneously is easily absorbed by the lymphatics and carried into the blood system) sets up a general disease resembling to a considerable degree in its anatomical features human scarlatina.

Furthermore, as respects the concern that cow's milk may have in the communication of disease—the consideration which led to the present investigations—we have some facts which appear to me to afford very suggestive indications for further pathological study. As I have pointed out on a previous page, it would seem that the milk pure does not contain the organism, but (whether or not this observation be confirmed) the milk during the act of milking is pretty sure to become contaminated by the fingers of the milker bringing down into the milk particles from the ulceration on the teat. The organism contained in these particles would find in the milk a good medium in which to multiply. Such milk would then practically correspond to an artificial culture of the streptococcus, such as we have found capable of setting up a general disease, when inoculated subcutaneously into calves. It is true we have as yet no experience of the inoculation of a known milk sub-culture into the human subject, but in the case of calves we have learnt that the general disease resulting from inoculation of an Agar-Agar sub-culture had characters closely allied to, if not identical with, human scarlatina. Then, feeding of animals with the cultures has not yet been tried, so that at present we are without information as to the characters of any disease that may be produced in calves by that means; whether or not calves fed with milk sub-culture of our streptococci exhibit the same pathological states as we have found to be produced by inoculation of calves with an artificial culture—states that bear so marked a resemblance to those of scarlatina in the human subject. In order completely to understand these and other relations, more experiments are required, and these I hope soon to have an opportunity of making.

Until I am in a position to state at greater length the peculiarities of the infective phenomena of the disease under consideration, I refrain from further comment on its various interesting and promising aspects.

THE BRITISH ASSOCIATION

SECTION E

GEOGRAPHY

Opening Address by Major-General Sir F. J. Goldsmid, K.C.S.I., C.B., F.R.G.S., President of the Section

However diffident I may feel in undertaking the duties of President of the very important Section of Geography at this anniversary, I have no right to take shelter under that diffidence for any shortcoming in the fulfilment of my task. All I would seek at your hands is indulgence for one whose training and antecedents have scarcely fitted him for appearing before you in a quasi-professorial capacity, and whose brief tenure of a Presidential chair at a meeting such as this must be regarded as rather an incidental passage in the annals of the British Association than a fair illustration of its *modus operandi*, or principle of selection in respect to its officers.

As to the subject of my opening address, I know none more befitting the occasion than the means of popularising the branch

[1] Referring to the commencement made in 1882 of investigation of the results producible in the cow by inoculation with the material of human scarlatina, see p. 67 of report of that year, I would propose that this study be extended without loss of time.

of science to which the meetings in this Section will be devoted, and thus attracting towards it that attention which it merits—nay which, in this our country if anywhere, it demands and necessitates.

The question is a wide one, but I will endeavour to narrow the field of its discussion to suit our purpose of to day, and keep within reasonable limits. A few words will suffice to lay before you the programme. It embraces: first, the uses of geography, an exposition of which should prove, and a due apprehension of which should admit, the necessity of its inclusion among the special studies of public schools; secondly, the mode of imparting a knowledge of geography so as to render it at once practical and engaging; and finally, such illustrations of modern travel and research as may serve to demonstrate how urgent is the study of geography to all classes in this country.

Before closing the subject, I shall endeavour to draw your attention directly, if somewhat cursorily, to the progress made by travellers and geographers in furthering what I may for the nonce describe as the objects of their profession during the past year, or since the last annual meeting of the British Association, at Aberdeen. But I shall only dwell upon such instances of geographical progress as from their character and locality come within the range of my personal experience, and serve to illustrate the main argument of this address.

To begin then with the uses of geography. There are doubtless many who will say demonstration here is superfluous, and that if its use was not admitted it would find no place in school studies, which is contrary to fact in many instances; there would be no primers or elementary works on the subject, whereas they may be reckoned by the score; books of travel would be rather entertaining than instructive, a charge which many recently published volumes would disprove; and so forth.

Some again will argue that its uses, such as they are, must be restricted to the few specialists who aspire to be geographers, and that for the million it is enough to carry about a rough idea of the four quarters of the globe, the principal countries and capitals in them, and a sufficient amount of preliminary instruction to understand Bradshaw and Baedeker. A third, and perhaps the largest category among educated people, consists of those who are indifferent to the whole question, and are content to find in geography either an honoured branch of science, or a mere nominal study, according to the views of the latest speaker, or most plausible reasoner. If it be allowable to apply things holy to things profane, no truer illustration of this class can be given than the Scriptural definition of men who receive seed "in stony places."

To the first of the above I would say that the place which geography holds among school studies is not that which it ought to hold if its uses were understood and appreciated. Primers and elementary books already published are good enough in their way, but the instruction they contain is not seriously imparted; and it may be that something fitter and more attractive to the beginner could be produced. At present all school-books on geography may be said, as a rule, to be consigned to the shelf of secondary subjects; and this is not the treatment which should be reserved for a study of such real magnitude. By and by it will be my endeavour to establish by argument and example the indisputable character of its importance.

For those who look upon geography as a profession which needs rather separate training than general education, and would prefer to leave its acquirement to travellers aiming at distinction, specialists in Government employ, and the more zealous and scientific Fellows of the Royal or any other Geographical Society, I can only express my regret that the delusion under which they lie unfits them so thoroughly to understand and much less satisfy the wants of a rising generation. By denying the universal character of the study they clearly misapprehend its true scope, and are dwarfing it to within the narrow limits of a conventional school task.

As a matter of State or public school education the science of geography should in truth be elevated, not degraded. In my humble opinion it should be placed on a par with classics, mathematics, and history, with each and all of which it has affinity. Undoubtedly there are accomplishments which come, as it were, of themselves, or are the outcome of lightly-sown seeds in the home. These for the most part are rather mechanical than mental, though some may have advocates to claim for them intellectual honour. But a knowledge of geography is not to be so acquired: it will not come like handwriting with incidental practice, nor is it to be gained by mere travelling. To move from place to place, whether across seas or continents, or both, to go round the globe itself and visit every important country and capital in the track chosen, even to prefer byways to railways, and search into obscure and hidden spots rather than those which are more generally frequented—all this process affords admirable matter for the note-book of the man of the world and observer, but will not educate in geography, unless the student himself has a serious purpose to turn his wanderings to the account of science. The cursory description which would apply to men and women, cattle and conveyances, hotels and caravansaries, restaurants, coffee-houses, and the like, in a moving panorama, is not always suited to bring out in bold relief the physical aspects of a country.

To the indifferent and wavering, to those who would wish to promote the study of geography if they could feel persuaded that it needs promotion, but who would leave to the better judgment and experience of others the decision on the whole question; to those who are content to accept the institution of a professorial chair in honour to the science, or to leave geographical study to the primitive teaching of their own childhood, whichever course be most in accordance with the temper or fashion of the times—I can perhaps do no better than appeal on the grounds of urgency—in other words, of the real importance of the cause for which, in common with abler and worthier advocates, I would now most earnestly plead. . . .

. . . I almost seem to be treading upon the threshold of platitudes when seeking to explain why geography should be useful to young men of ordinary culture, for whatever career they may be destined. In some cases it is naturally more urgent as a study than in others. The military man, for example, should be more or less a scientific geographer. His profession may require him to survey and describe new regions; and a campaign over a beaten track should find him acquainted with the minute topography and physical aspect of places, at least the names of which are familiar household words. The sailor should in like manner bear in mind the configuration and character of sea-coasts, and carry about the landmarks of his own observations as well as those to which he may refer in books. To both must geography be eminently a professional study. But, considering the enormous extent of our Indian Empire and colonies, and the many foreign States with which we must have intimate relations, is any Englishman, I would ask, competent to discuss, much less to serve, the interests of his country who knows nothing of the physical features, resources, products, population, and statistics of these? It seems to me to be the duty of every loyal subject and citizen, high or low, rich or poor, to seek information on these heads wherever it may be obtained.

But of all men who should realise geography in its broad, comprehensive sense—both as an aid to history, and as a science to which history may be subordinate—first in order is the statesman, in whose province falls the disposal and partition of countries or regions. What should we say of the judge—we may be thankful there are none such on the English bench—who not only gave his decision without mastering the merits of the case before him, but who was also ignorant of the law and precedents which should guide him in the treatment of those merits? The argument might apply with equal force to other callings from the members of which professional opinions or decrees are required by their fellow men. Why, the evil would be so great and so palpable that its existence would not be tolerated for a single day: and the only reason why it *is* allowed to prevail in matters geographical is that though equally great in respect of these it is not equally palpable. The statesman may not know the situation of this or that particular palce, nor its products and resources, but neither does the public. One is not taught geography any more than the other; so that while ignorance and error are brought to bear on a spurious judgment, the critic is not in a position to point out the real flaw, and the blunderer escapes the scathing condemnation which would otherwise await him in the columns of the morning paper.

Let us suppose a case by way of illustration—a case which conveys no exaggerated idea of what happens, or may happen in the course of a year—a case which without being an actual occurrence has in it the flavour of actual occurrences. There is a large tract of land in the far West or far East, it matters not which. All that is known about it is that it is called Laputa or Barataria, and that it is situated in the central part of a region or continent so vast that it might be reasonably called the largest quarter of the globe. Well: it is encroached upon by a powerful neighbour, and England requires the preservation of that land's integrity

and independence. Her best instructors on the matter have told her that such is her interest, and she believes them. Intervention, therefore, becomes necessary; negotiations ensue; and the whole question revolves itself into a partition of territory and demarcation of boundary—in other words, the question becomes one of geography—what I should call, for reasons to be explained hereafter—Political Geography. Who, if not the ruling statesman, should know the true principle on which to deal with a large settlement of this nature—one, it may be, involving ethnological, commercial, humanitarian, quite as much as territorial, considerations? Who, if not the agent on the spot, should know the details to regulate the application of the principle? But the statesman should be in full possession of his agent's details, and be capable of appreciating them not only from the latest reports supplied, but from a certain insight into the matter obtained from early study. He should have been coached in that comprehensive kind of geography which would have embraced the particular information required. Under present arrangements it is not so. The geography taught at schools is too simple or too scientific—too complex or too superficial; in any case it is not the geography which would benefit the Cabinet Minister in solving a territorial difficulty any more than would those "ingenuæ artes" which have so strong a civilising influence on the natural man. Experience in classics may forestall the faulty quotation and false quantity, but fail to suspend the false move on the political board. And it need not be said that, while the first, in point of fact, affects the speaker only, the last concerns the happiness of the million.

We now reach the second consideration: the mode of imparting a knowledge of geography so as to render it at once practical and engaging; and I may be pardoned if I dwell upon this somewhat lengthily, for it involves the gist of the whole question before us. It is always easier to detect a flaw than to find a remedy, and in the present case the flaw is generally admitted by experts. There may be differences of opinion on its character and extent, but apparently there are none on its existence. I shall have to recur to the first, but would ask leave to dismiss the last as established. We are told on excellent authority that in our own country the elements of success in geography are wanting, and the conclusion has been practically accepted by the representative Society of this branch of knowledge. The remedy has been suggested, and in a certain sense partially applied, but a great deal more remains to be done, and the many views entertained and expressed by competent men on the claims and requirements of geography in England render necessary a short review of what may be called the "situation," including notice of work achieved in the direction of reform. . . .

Of late years the Royal Geographical Society, in pursuance of its originally expressed aims and objects, and strong in the experience of a long and prosperous career, has endeavoured to arouse the rising generation to a sense of their shortcomings as regards the particular science in the promotion of which it has its own *raison d'être*. It granted prizes to such public schools as chose to compete for them, and after sixteen years' trial discontinued the grant, owing to unsatisfactory results. It opened correspondence with schools and colleges, and made other judicious and laudable attempts to evoke sympathy and support. But all its proceedings have been as it were preliminary, and may be considered rather as foundation-stones of a temple of success than the outer walls or any visible part of the building itself. A more recent attempt to reach the masses was the Exhibition of Educational Appliances. Objects used in geographical instruction at home and abroad were collected and arranged in galleries hired for the occasion, and the public were invited to inspect them. At the same time appropriate lectures were periodically delivered, by competent and experienced men, to the visitors, many of whom were not merely interested amateurs, but persons actually engaged in school teaching. Attention was called to the fact that the Exhibition was purely educational; that there were in it specimens of German, Austrian, and Swiss maps, executed with a finish and detail unusual in our school maps at home; but that as the Society's inquiry embraced Universities as well as schools, part of the appliances exhibited were used in Continental Universities, though in reality some of the finest maps shown were found also in the higher schools of Germany and Austria. Besides maps, there were in the collection globes, models, and text-books, the presentations not being confined to countries visited by the inspector, to whom the task of collection had been intrusted, but from others also; and these were further supplemented by contributions from British publishers.

The result of this new departure—if the term be allowable—was pronounced very satisfactory, and at the close of the Exhibition, or in the spring of the present year, the Council considered what would be the next best step to take in furtherance of their desire to raise the character of geographical study. At a later date, on the recommendation of their Educational Committee, they resolved on addressing the Universities to the effect that chairs or readerships be instituted similar to those which were at that time filled in Germany by Carl Ritter at Berlin and Profs. Peschel and Richthofen at Leipzig. In carrying out the resolution alternative schemes were submitted. The Council would appoint, under approval of the University authorities, a lecturer or reader in geography, paid out of the Society's funds, he being accorded a fitting local status; or each University might join with the Council in the matter of payment, and a reader be appointed by a committee on which the Society should be represented. . . .

It will thus be seen that special efforts have been made and continue to be made to popularise a science which has never, so far as can be ascertained, held its proper place in the educational programme of our schools or Universities. We must not, however, lose sight of one important consideration. More remains to be done than to institute a chair, a professorship, a readership. It must be clearly understood on what general lines of study we are about to proceed. Is geography to be taught in its full, comprehensive sense, as something involving a knowledge, more or less, of mathematics and astronomy, of ancient and modern history, of ethnology, zoology, botany, geology, of men and manners, laws of nations, modes of government, statistics and politics, something requiring in the disciple a quick ear, a searching eye, an appreciation of scenery and outer subjects as well as physical aspects of country, a power of picturesque but an adherence to accurate description? If so—and I believe I have only stated the qualifications of the travelled and finished geographer—would it not be well to inquire whether the component parts of the science should not be reconsidered, and a subdivision effected which would make it easier to deal with than geography as now understood, under the terms physical, political, and perhaps commercial? . . .

Not six months ago I wrote as follows:—"We are authoritatively told that, at one of our greatest public schools, which may be fairly taken as representative of its class, there is no systematic teaching of geography at all, but 'that in the history lessons, as well as in the classical lessons, a certain amount of geography is introduced incidentally.' Again, if we look at the Universities abroad, it has been found the custom, until quite lately, both in France and Germany, to combine the chairs of geography and history under one professor. Now the 'incidental' character of geographical instruction is a tacit declaration of its unimportance, which every day's experience shows to be without warrant; and its combination with history may be an expedient to render it less distasteful than it appears as a separate study. But a useful hint may be taken from the Continental practice, and a partial fusion of two departments effected, which would commend itself to common-sense, and, to judge from the recorded opinions of certain of our educational experts, might not be objected to by head masters in England collectively. Let us, then, endeavour to extract from the lessons of conventional geography that part which is inseparable from the study of nations and people, and place it under a new and more appropriate head. In this view, so-called 'political geography,' stripped of its purely scientific belongings, would be taught in connection with history, and made an essential ingredient in the early training of British statesmen, whose after-reputation should be more or less the outcome of a University career, the grounding of a public or grammar school, or private tuition. It is difficult to reconcile the amalgamation of what may be considered 'scientific' geography with history. One is as thoroughly apart from the other as geology is from astronomy."

The meaning of the verbal combination "political geography" requires some kind of analysis. Conventionally, and in an educational sense, it is the description of the political or arbitrary divisions and limits of empires, kingdoms, and States; their inhabitants, towns, natural productions, agriculture, manufactures, and commerce, as well as laws, modes of government, and social organisation—everything being viewed with reference to the artificial divisions and works made by man. Accepting this interpretation of its objects, who can hesitate to admit its palpable and immediate relation to history? The mathematical science which investigates the physical character of territory and territorial boundaries is in this case but a secondary requirement, and

can be always fairly disposed of in the recognition of results. Otherwise, we have simply commercial geography with ethnography, and considerations which we may call political in the present but which are undoubtedly historical in the past. Surely, then, it would be wise and reasonable to combine the studies of history and political geography—putting a wider interpretation than the conventional one upon the latter designation in such a manner that the two together should be just the sort of *pabulum* dispensed to the rising generation of statesmen, diplomatists, and all who aspire to the name of politician, in its higher sense of capability to promote as well as to discuss the national welfare.

And admirable lecture on "Geography in its Relation to History" was delivered by Mr. James Bryce—the late Under-Secretary for Foreign Affairs—in connection with the recent London Exhibition of Geographical Appliances. Those who are acquainted with it will readily understand why I pause to remark on its enlightened teaching; to those who have not that advantage I would explain that it seems to embody the arguments of Modern Thought on the important question we are now considering, and that a brief allusion to it is therefore no irrelevant introduction here. The lecturer, seeking to demonstrate that history and geography touch one another in certain relations and interests, laid down the proposition that man is, in history, more or less "the creature of his environment"; that "on one side, at all events, he is largely determined and influenced by the environment of nature"; and that "it is in discovering the different effects produced on the growth of man as a political and State-forming creature by the geographical surroundings in which he is placed" that one point of contact is found. He, moreover, maintained that man, "although he may lift himself above his environment, cannot altogether escape from its power." Dividing the influences thus exercised into three classes, he showed that those arising from the configuration of the earth's surface affected movements of races, intercommunications, and barriers of separation; that those belonging to climate affected the occupation or abandonment of particular localities on the score of health, fertility, or non-fertility of soil, and consequently commerce and cultivation; and that those which owed their existence to natural products unmistakably directed the energies of peasantry and people into certain fixed channels of enterprise—a result which applies to the zoology as well as to the mineral and agricultural resources of a country. He made the very true observation that the "animals affect man in his early state in respect to the enemies he has to face, in respect to his power of living by the chase, in respect to the clothing which their furs and skins offer to him, and in respect to the use he is enabled to make of them as beasts of burden or of food"; and he therefore concluded that "zoology comes to form a very important part of the environment out of which historical man springs." A volume might well be written on this suggestive theme alone; and if, as I believe, the proposition of a human being's dependence on environment be admissible in its entirety, what a field of speculation is open to the inquirer! A condition held applicable to the unreckoned millions of to-day must have had a marvellous effect in giving character to original Man!

This conception of man's environment supposed heads or branches of geography, all bearing upon history, which might be distinguished by names such as ethnological, sanitary, commercial, linguistic, political and military, legal—the last leading to the consideration of the Suez Canal and sea-channels in which several States have interests. As time, however, will not allow me to quote the lecturer's apt and well-put illustrations which followed, I may mention that the express object with which they were introduced was to show how "the possession of geographical knowledge, and a full grasp of the geographical conditions" with regard to some of the leading countries of the world, "will enable a person studying their history to make the history more intelligible and real." In strict conformity with this opinion, and in the conviction that the want of geographical knowledge and "full grasp" of geographical conditions will betray men in power to commit dangerous mistakes, calculated to injure the national prestige and credit, and men out of power to become their upholders in error, I would express the hope that, in any future arrangements which may be perfected for the better education of our countrymen, while physical and scientific geography are invested with a degree of prominence and honour to which they have hitherto never attained, that branch of study which we have been accustomed to call political will be reconsidered and, if necessary, newly defined by competent men. The conclusion at which I have myself arrived—one which I am quite ready to abandon before the arguments of sounder reason—is that we have here something which belongs mainly to history, and, in such light, its scientific should be separated from its non-scientific elements. A partition should be made which would equally suit the mind of the student whose tendencies are rather towards metaphysics than mathematics, as of him who is a votary of practical science only. I do not presume to touch upon the action of Universities, except to say that I can conceive no better example could be afforded that the intellect of England had due regard for the material interests of England than by the creation of a chair for scientific geography and the relegation of that which is non-scientific to the chair of history. . . .

Time warns me that I have detained you long enough, and that if my illustrations apply to the argument intrusted to your consideration, the application should at once be made evident. To my own mind the bearing is clear. A Boundary Commission represents the three branches of Science, Research, and Diplomacy—in other words, all that comes under scientific geography and political geography. The first, you will understand, comprises the survey of country, mapping, and determination of localities. The second has to do with the definition of territorial limits, and, in such sense, with history, ethnology, and laws of nations. That all this has been done, and well done, on the present occasion is not disputed, any more than that enlightened attention will be given to the due disposal of results. But are not these matters of sufficient importance to be taught as daily lessons in our schools, and presided over in University chairs? Even those barren and desolate lands of which we have now spoken—and I have myself traversed many miles of such, some, indeed, in the near vicinity of the Perso-Afghan frontier, between Herat and Farah—they may have a meaning which can only be understood by the initiated, by those who have made them a long and seriously-undertaken study. To the many they are but miserable deserts displayed in incomplete maps; to the few they may have a value far beyond their outer show. Were I asked to sketch out the kind of manual which might be useful in preparing officers for dealing with questions such as these, I would solicit reference to a late paper which I contributed to a quarterly journal, and which I have once before quoted. In it I stated:—

"Asia itself is a stupendous study, but the difficulties may be smoothed to the learner by the judicious employment of method which, after disposing of essential generalities, would naturally tend to division and subdivision. The first would imply a region such as Turkestan; the second, a group of States or single States only, such as Bukhára and Khiva. Given, then, a particular area, the next consideration should be to explain its physical geography. This should comprise the scientific description of its mountains, rivers, and valleys. Its geography should be comprehensive in respect of direction, elevation, watersheds, and connection with plains and plateaus; its hydrography should treat of sources and mouths, basins, drainage, and connection with lake and swamp. Climate and the more important forms of animal and vegetable life should follow in due course; indeed, something of geology, zoology, and botany, and it may be more besides, might reasonably be added to satisfy the requirements of purely scientific teaching. After science, history would follow, and, joined to history, an account of the religion, manners, and customs of the people, as affected by the historical narrative; a statement of the artificial lines of separation which have replaced natural boundaries in consequence of the wars, revolutions, or arbitrary changes which have characterised certain reigns or epochs; an exposition of the form or forms of government in vogue at different periods; and, finally, a chapter on trade and commerce, including a notice of indigenous products and manufactures. Maps, applicable to relations of territorial changes, would be of immense value; and an historian's criticism on these relations, if offered in that fair spirit which alone is justified in composing history, would be an indispensable complement." . .

REPORTS

Second Report of the Committee, consisting of Prof. Balfour Stewart (Secretary), Sir W. Thomson, Sir J. H. Lefroy, Sir Frederick Evans, Prof. G. H. Darwin, Prof. G. Chrystal, Prof. S. J. Perry, Mr. C. H. Carpmael, Prof. Schuster, Capt. Creak, and Mr. G. M. Whipple, appointed for the Purpose of

Considering the Best Means of Comparing and Reducing Magnetic Observations. Drawn up by Prof. Balfour Stewart.—It is with deep regret that the Committee record the death of one of their number—Capt Sir Frederick Evans, so well known for the valuable contributions which he had made to terrestrial magnetism. His eminent scientific qualities combined to make him a greatly esteemed member of this Committee, who now deplore his loss.

The Committee have added to their number the following gentlemen:—The Astronomer-Royal, Mr. William Ellis, Prof. W. G. Adams, and Mr. W. Lant Carpenter. They could hardly consider their list complete without the addition of the first two names, and they are glad that, although not members of the British Association, these gentlemen were not unwilling to serve on one of its Committees.

Since the last meeting of the Association Mr. G. M. Whipple has made a comparison between the method of obtaining the solar-diurnal variation of declination adopted by Sir E. Sabine and that of Mr. Wild. These methods were applied to three years' observations at the Kew Observatory, and the results were compared with those deduced by the Astronomer-Royal from the same three years at Greenwich. The comparison will be found in Appendix IV. to this report.

The Committee think that this comparison deserves careful study, but they do not feel themselves able to pronounce as yet upon the comparative merits of these various methods. Nevertheless, they are of opinion that it is highly desirable to record the daily mean values (undisturbed) of the three magnetic elements side by side with their solar-diurnal variations.

It will be seeen by Appendix III. that Sir J. Henry Lefroy has continued his comparison of the Toronto and Greenwich observations. He has obtained from the smooth curves—that is to say, taking Mr. Wild's method—results which appear to show that the turning-point of the declination is decidedly later in local time at Toronto than at Greenwich. Sir J. H. Lefroy attributes this to the fact that these two stations are on different sides of the Atlantic.[1]

Appendix II. exhibits, by aid of a diagram, an interesting comparison of Senhor Capello between the diurnal variation of the inclination and that of the tension of aqueous vapour. It is remarkable to notice the great similarity between these variations; a similarity which holds separately for each month of the year. Senhor Capello hopes that these results may be confirmed by a more extended series of observations.

The researches to which allusion has now been made refer to the solar-diurnal variation, excluding disturbed observations. With respect of disturbances, Sir J. Henry Lefroy has continued his comparison of Toronto and Greenwich, and his results are indicated in Appendix III.

Prof. W. G. Adams has, it is well known, made, in connection with another Committee, extensive comparisons between the simultaneous traces of magnetographs in various places. He is at present engaged on such an undertaking, and the Committee are in hopes that when this is completed he will give them the benefit of his experience. The subject is an extremely interesting one, and it seems not impossible, judging from the Greenwich results as obtained by Sir G. B. Airy, that magnetic disturbances may be in a great measure due to earth-currents, so that an easy approximate method of recording the latter may be obtained from magnetograph indications.

The Rev. S. J. Perry and Prof. Stewart (Appendix V.) have completed their preliminary comparison of certain simultaneous fluctuations of the declination at Kew and at Stonyhurst in a paper which has been published in the *Proceedings* of the Royal Society, No. 241, 1885. The results are virtually those which were stated in the last report of the Committee. The comparison is being continued and extended.

Prof. Stewart and Mr. W. Lant Carpenter (Appendix VI.) have given the results of other four years' reduction of Kew declination disturbances classified according to the age of the moon. These are very similar to the results of the first four years given in our last report. The same observers give a comparison, extending over four years, between declination disturbances and wind values, which appears to them to show that there is some relation between these two phenomena. They are anxious to continue and extend both these inquiries.

Prof. Stewart has pointed out certain general considerations which appear to indicate that the solar-diurnal variation may perhaps be caused by electric currents in the upper atmospheric regions. Dr. Schuster has likewise made a preliminary application of the Gaussian analysis, tending to confirm the hypothesis that currents in the upper regions are the cause of these variations.[1]

By this analysis Dr. Schuster obtains certain relations between the solar-diurnal variations of the three magnetic elements which ought to hold on the hypothesis that these variations are caused by currents in the upper atmospheric regions. One of these is that the horizontal force component of the daily variation ought to have a maximum or minimum at the time when the declination component vanishes—that is to say, attains its mean position. Another is that the horizontal force ought to be a maximum in the morning and a minimum in the afternoon in the equatorial regions, while in latitudes above 45° the minimum ought to take place in the morning. A third is that in the equatorial regions the maximum of horizontal force ought to be coincident with the minimum of vertical force, and *vice versâ.*

These conclusions are sufficiently well confirmed by observations, and thus render hopeful the first attempt to apply the Gaussian analysis to the solar-diurnal variation.

The appendices of Capt. Creak (I.) and of Dr. Schuster (VII.) have reference to this subject, and indicate the importance of some action being taken by the Committee to prepare for a thorough application of the Gaussian analysis to the magnetic variations. It will be seen from the remarks of Dr. Schuster that some time must elapse before observations are obtained sufficiently good and complete to justify a systematic application to them of mathematical analysis. This circumstance has induced the Secretary to lay before this Committee in Appendix VIII. a provisional working hypothesis regarding the cause of the periodic variations of terrestrial magnetism which has gradually grown up by contributions from various quarters.

While this Committee do not hold themselves responsible for the various statements contained in this hypothesis, they would point out the desirability of ascertaining to what extent well-known magneto-electric laws may succeed in accounting for the phenomena of terrestrial magnetism, and likewise the desirability of ascertaining to what extent the magnetic earth appears to be subject to the laws of ordinary magnets.

A preliminary working hypothesis of this nature might serve to elicit facts while the material for the Gaussian analysis is being completed, and it would add to the interest of the final result if we should obtain reason to think that electric currents in the upper atmospheric regions are at once the *immediate causes* of magnetic variations and the *effects* of atmospheric motions in these regions, so that a knowledge of the one set of currents might possibly enable us to determine the other.

Finally, in Appendix IX. we have a list drawn up by Sir J. Henry Lefroy of the various stations where magnetic observations of any importance have been made.

The Committee have drawn 10*l.* 10*s.*, and returned to the Association a balance of 29*l.* 10*s.* They would desire their re-appointment, and would request that the sum of 50*l.* should be placed at their disposal, to be spent as they may think best on the researches mentioned in this report.

Third Report of the Committee, consisting of Prof. Balfour Stewart (Secretary), Prof. Stokes, Prof. Schuster, Mr. G. Johnstone Stoney, Prof. Sir H. E. Roscoe, Capt. Abney, and Mr. G. J. Symons, appointed for the Purpose of Considering the Best Methods of Recording the Direct Intensity of Solar Radiation.—The Committee, in conformity with their last report, have had constructed by Mr. Casella an instrument of the following description:—It consists of a thick-sided copper cube, one side of which is to be exposed to the sun. In the thickness of this side are inserted two thermometers; a third is put in the side opposite; while the bulb of a fourth occupies the hollow centre. If the readings of these instruments are found to have any constant relation, the fourth instrument will be replaced by a flat bulb thermometer exposed to the sun's rays through a hole in the sun-ward side of the cube. The Committee suggest that they be re-appointed, and that the sum of 20*l.* be again placed at their disposal.

From the Report of a Committee, consisting of Profs. G. H. Darwin and J. C. Adams, for the Harmonic Analysis of Tidal Observations. Drawn up by G. H. Darwin.—Major Baird's "Manual of Tidal Observations" is now printed, and will be

[1] See Appendix by Sir G. B. Airy to the Greenwich Observations, 1884.

[1] An account of these researches will be found in the *Phil. Mag.*, April and May 1886.

sold by the British Association, 22, Albemarle Street, W. The Indian tidal results of all previous years, and those given in the various reports to the British Association, have been reduced by Major Baird to the standard form recommended in the report of 1883. To these have been added the results derived by the United States Coast Survey, and the whole has been published in the *Proceedings* of the Royal Society, No. 239, 1885, in a paper by Major Baird and Prof. Darwin. In the course of the Indian tidal operations a discussion has arisen as to the determination of a datum-level for tide-tables. The custom of the Admiralty is to refer the tides to "the mean low-water mark of ordinary spring tides." This datum has not a precise scientific meaning, as the diurnal tides enter into the determination of the datum in an undefined manner; and it follows that two determinations, both equally defensible, might differ sensibly from one another. A datum-level should be sufficiently low to obviate the frequent occurrence of negative entries in a tide-table, and it should be rigorously determinable from tidal theory. It is now proposed to adopt as the datum-level at any new ports in India, for which tide-tables are to be issued, a datum to be called "the Indian spring low-water mark," and which is to be below mean sea-level by the sum of the mean semi-ranges of the tides M_2, S_2, K_1, O ; or, in the notation used below,—

$$H_m + H_s + H' + H_o$$

below mean water-mark. This datum is found to agree pretty nearly with the Admiralty datum, but is usually a few inches lower. The definition is not founded on any precise theoretical considerations, but it satisfies the conditions of a good datum, and is precisely referable to tidal theory. If, when further observations are made, it is found that the values of the several H's require correction, it is not proposed that the datum-level shall be altered accordingly, but, when once fixed, it is to be always adhered to. The report then shows how harmonic analysis might be applied to the reduction of a short series of tidal observations, such as might be made when a ship lies for a fortnight or a month in a port. The method has been applied by Mr. Alnutt to the computation of tide-tables at Port Blair and several other ports, and the computed results are compared with those given both by a rigorous instrument and by actual observation. It is remarked that, while better agreement was to be desired, the errors are inconsiderable fractions of the whole intervals of time and heights under consideration. An attempt made to detect the nineteen-yearly tide by observations at Karachi has led to the belief that it is extremely improbable that this important datum will ever be detected.

P. T. Main presented a *Report on our Experimental Knowledge of Certain Properties of Matter*.—The report discussed recent work on the testing of Boyle's law for very low as well as for very high pressures, the researches of Amagat and C. Bohr being included. It then passed to the verification of Gay-Lussac's law. Recent researches on the saturated pressures of vapours at various temperatures, especially those of Ramsay and Young, were next considered, especially to determine (1) whether statical and dynamical methods of observation lead to similar results ; (2) whether the pressures of ice and of water-vapour are the same at the same temperature. The important question of the pressure of mercury-vapour, and modern research in the determination of the critical points of nitrogen and other gases, and in the measurement of vapour-densities, were also included.

Prof. George Forbes presented the *Report of the Committee on Standards of Light*.—The Committee had met repeatedly during last winter. It had been proposed in last year's report to carry on experiments on electrical standards in the hope of arriving at an absolute standard of light. One of the first steps was to discover a means of reproducing a definite temperature, and certain experiments were proposed for this purpose. At one of the first meetings of the Committee Capt. Abney announced that he had already found a means of doing this in a different manner to that proposed in the Committee's report, and depending only upon the change of resistance of the carbon filament. Under these circumstances the Committee left this part of the experimental investigation to be reported upon by Capt. Abney. His further researches had, however, led him to believe that the law which he had announced to the Committee did not hold with all qualities of carbon filament. He had, however, been engaged upon further experimental researches, which were almost ready for publication, and which had an important bearing upon the labours of the Committee. In last year's report attention was drawn to the value of the pentane standard of Mr. Vernon Harcourt as a practical reproducible standard, and Mr. Rawson had been since then engaged in a further examination of that standard. Sir James Douglass had also made some experiments which were not quite completed, but had gone so far as to give great promise. Some account of the experiments in that report had been expected by the Committee, but the absence of Sir James Douglass on official business had interfered with this. At one of the first meetings of the Committee the Secretary showed what he had done in the way of improving thermopiles such as it was hoped would be of use in the investigations recommended in last year's report, and he was instructed by the Committee to proceed with the construction of the instrument, which had been completed, and was now to be placed before the Section and described in a separate paper. The Committee requested to be re-appointed, with a grant of 25*l*.

Report of the Committee on Electrolysis, presented by Prof. Oliver J. Lodge (Secretary).—The report, which was only an interim report, stated that only one meeting had been held, but a large amount of correspondence had passed, as well as work done by the various members. This work was discussed in separate papers. The Committee asked to be re-appointed with a grant to defray the expense chiefly of printing selected memoirs, and of getting pure substances.

Report of the Committee on English Channel Tides.—The Committee had received the records of the self-recording tide-gauges at Dover and Ostend for the four years 1880 to 1883. These are so bulky that they content themselves with discussing in an appendix to the report the records of four periods of a fortnight in the year 1883, namely, at the solstices and the equinoxes. Of these diagrams were shown. The Committee suggest that they hand over their papers and records to the Committee for the Harmonic Analysis of Tides.

Prof. Johnson submitted the *Report of the Committee formed in Canada to establish a System of Tidal Observations in that Country*.—He said they had communicated with the Government in the matter, and while, owing to the expense at present incurred in hydrographical work on Lake Ontario and elsewhere, the Government had not yet given their consent, it was hoped that before long their object would be attained. The Committee asked for re-appointment.

Report of the Electrical Standards Committee, presented by Mr. Glazebrook (Secretary).—Eighteen standard coils have been tested during the year, and certificates of their value issued. The attention of the Secretary was called to the fact that the paraffin in some of the coils showed a trace of green coloration round the edges. This has been shown to arise from the action of a small amount of acid, left in the paraffin, on the copper of the case and connecting-rods, and the Committee are considering how to deal with the difficulty. At present the insulation resistance of the coils is extremely high, amounting to as much as 8000 megohms. The Committee wish to express their sense of the great desirability of establishing a National Standardising Laboratory for Electrical Instruments on a permanent basis, and their readiness to co-operate in the endeavour to secure the same. The Committee apply for re-appointment, with the addition of the name of Mr. J. T. Bottomley.

Second Report on the Fossil Plants of the Tertiary and Secondary Beds of the United Kingdom, by J. S. Gardner.—Attention has been devoted exclusively this year to the fossil flowering or phanerogamous plants. The results point to the conclusion that while the Gymnosperms, to which the Coniferæ belong, are of the highest antiquity, there are no angiospermous plants in British rocks older than the Secondary, if we except the problematic plant known as *Spirangium*. Even so late as the Lias no indisputable Angiosperm has been discovered within our area, for the supposed Monocotyledons from the Rhætics, near Bristol, hitherto referred to the family of Pond-weeds under the name *Najadita*, are really cryptogamic plants of the moss tribe, closely allied to the river moss *Fontinalis*. This group had not previously been found fossil, and, so far as it goes, would indicate rather a temperate climate. It is important to notice that these conclusions are shared by Prof. Williamson, Mr. Carruthers, and by all botanists who have examined them, as well as by Mr. Brodie, the possessor of the specimens. The *Lilia*, *Bensonia*, and other supposed Monocotyledons of similar age are very imperfectly preserved, and doubtless referable to Cycads, a family which abounded then.

We have examined a large number of specimens of the anomalous Jurassic plant described by Carruthers as *Williamsonia*. Though there are still many difficulties in the way, our own examination of the specimens in London, Manchester, Cambridge, and elsewhere tends to confirm Saporta's view, referring them to the group of *Pandanaceæ*, so far as that there does appear to be vestiges, in some cases at least, of lignitic structure which may represent the areolæ or carpels. These rather minute cavities and the lignitic matter surrounding them fall away on exposure to the air, and only traces of them are visible. Should Saporta's contention be upheld, *Williamsonia* will be by far the most perfectly known of the Secondary Angiosperms, since all the organs of fructification and even of foliation are more or less known.

A still more definite Monocotyledon is the *Podocarya*, from the Inferior Oolite, originally figured by Buckland, and redescribed by Carruthers. Its resemblance to the fruit of *Williamsonia*, as interpreted by Saporta, is extremely striking, and on suggesting this to that author, he replied that he was in the act of preparing an important work on the very subject. The same work is to include an illustration of the most recent member of the group, obtained from the Grey Chalk of Dover, and which we thought advisable to communicate to him.

Next in point of age, among English Monocotyledons, to the *Podocarya* is the *Kaidacarpum*, from the Great Oolite, also described by Carruthers, and by him referred to the *Pandaneæ*. We have been able to ascertain that a second species, hitherto supposed to be of Cretaceous age from the Potton Sands, is a derived fossil, and undoubtedly Jurassic. A third species was originally figured, without any reference in the letter-press as to its age or locality, by Lindley and Hutton as *Strobilites Bucklandi*; this, however, is far more likely to prove a Jurassic than a Cretaceous fossil if found, and the genus should not be included in lists of plants of the latter age.

The oldest Monocotyledons thus appear to be referable to the *Pandaneæ*, a group of plants distributed in widely distant and remote oceanic islands, and whose fruits are still met with at sea in drifts of vegetable matter.

Next to these in antiquity are two very monocotyledonous-looking fragments from the Jurassic of Yorkshire, which have been fully described in the *Geological Magazine* for May and August. The one is apparently an unopened palm-like spathe, and the other a jointed cane-like stem. Mr. Brodie possesses an undoubtedly monocotyledonous leaf-fragment from the Purbeck of Swindon.

The *Aroideæ* have long been supposed to be a group of very high antiquity, but there are good reasons for believing that the supposed remains of aroideous plants from beneath the Tertiaries are, without exception, referable to other groups, and actually there are no known traces of them earlier than the Middle Eocene, when they become by no means uncommon.

In a similar manner the fruits once supposed to represent *palms* in the Palæozoic and Mesozoic rocks have been gradually removed or suppressed, and, unless the fragments of palm-like wood in the Gault at Folkestone are taken into account, there are no traces of palms in any of our Secondary strata. They, however, appear as low down in our Eocene as the Woolwich series.

The supposed liliaceous or *Dracæna*-like stems from the Wealden, so frequently mentioned by Mantell, are not easy now to identify; but it is very probable that certain stems of *Endogenites* in the British Museum are those intended, in which case they are of course cycadeous. The Wealden has, indeed, so far yielded no trace whatever of any more highly organised plants than ferns and Gymnosperms, and this, when we consider that Monocotyledons were undoubtedly in existence, is a fact that should be of great significance to speculative geologists. The sediments must represent the deposits of the drainage system of a large area, for they are of vast extent and thickness, varied in character, and abounding in remains of trunks and stems, fruits and foliage of plants. In them, therefore, if anywhere, we might reasonably expect to find at least the traces of reed and rush, but the swamps seem to have been tenanted only by Equisetum and ferns, and the forests by Cycads and Conifers.

Angiosperms are absent throughout the Neocomian and Gault of Britain; and it is only in the White Chalk that we meet with any indications of them.

Of the gymnospermous section of Phanerogams the records are very different. To refer here to the earlier Secondary Coniferæ and Cycadeæ would be quite beyond our province, and it is only those of the Cretaceous, as the last discoverable ancestors in our area of the Eocene flora, that are of immediate interest. These belong, excluding Cycads, chiefly to the newest section of the Coniferæ, the Pine family. We are able to make the following contribution to our knowledge of these:—*Pinites Andraei*, Coemans (Gault, Folkestone); *P. Valdensis*, sp.nov. (Wealden, Brook Point, Isle of Wight); *P. Carruthersi*, sp.nov. (Wealden, Brook Point, Isle of Wight); *P. cylindroides*, sp.nov. (Lower Greensand, Potton); *P. Pottoniensis*, sp.nov. (Lower Greensand, Potton). These are described and figured; the report then gives a list of thirteen species of British Cretaceous Coniferæ previously described.

Passing to the Tertiary forms the report refers to leaves in the basement bed of the London Clay at Colden Common, between Bishopstoke and Winchester: the blocks of clay in which the leaves occur are derived, but the plants are allied to the Alum Bay flora; there are no palms.

Much work has been done in collecting at Sheppey, but there are great difficulties in the way of determining the fruits.

A large series of leaves of *Smilaceæ* has been obtained from Bournemouth, by means of which the number of good species is now reduced to five.

The leaves of *Smilaceæ* are highly characteristic, and can be determined with a large degree of certainty; but it is quite improbable that such will be the case with very many of the families of Dicotyledons.

Fortunately fruits and even flowers are comparatively abundant at Bournemouth, and we consequently anticipate little difficulty in determining leaves belonging to such easily distinguishable fruits as *Alnus*, *Tilia*, *Acer*, *Carpinus*, the *Leguminosæ*, and many others, but the residuum with indeterminable fruits, or fruits that will not float, may be very large. We are thus brought to the question, whether any value beyond that of mere landmarks, or aids to the correlation of rocks, can be attached to the determinations of fossil dicotyledonous leaves arrived at when fruits are absent. Nearly every Tertiary and even many Cretaceous floras are said to comprise *Quercus*, *Fagus*, and *Corylus*, to select these as typical examples. Now, we very much doubt whether the fruits of these genera have been met with in any strata older than the Upper Miocene, we might almost say the Pliocene; whilst in the latter the fruits of at least two of them are very far from uncommon. Fossil hazel-nuts are well known to abound in forest beds such as the one at Brook, in the Isle of Wight, and at Carrickfergus. It does appear to us that it would have been wiser and more consistent, when arriving at these determinations, to have taken the absence of fruits into account, when these were such as would naturally have been preserved. The large proportion of fossil dicotyledonous leaves that have been referred without any hesitation to living genera, must strike every one, in comparison with the relatively few associated fruits that have been determined otherwise than as Carpolithes—a name which is a confession of failure. It will thus be seen that in our opinion the fossil Dicotyledons of our own Eocene must be dealt with in a manner different from that pursued by the majority of foreign writers on kindred subjects, and that a revision of much of their work is urgently needed.

Report on the Caves of North Wales, by Dr. H. Hicks, F.R.S.—The explorations have been confined to the caverns of Ffynnon Beuno and Cae Gwyn, in the Vale of Clwyd. Among the remains discovered in these two caverns up to the commencement of the work this year there were over eighty jaws belonging to various animals, and more than 1300 loose teeth, including about 400 rhinoceros, 15 mammoth, 180 hyæna, and 500 horse teeth. Other bones and fragments of bones occurred also in very great abundance. Several flint implements, including flakes, scrapers, and lance-heads, were found in association with the bones. The most important evidence, however, obtained in the previous researches was that bearing on the physical changes to which the area must have been subjected since the caverns were occupied by the animals. During the excavations it became clear that the bones had been greatly disturbed by water action, that the stalagmite floor, in parts more than a foot in thickness, and massive stalactites had also been broken and thrown about in all positions, and that these had been covered afterwards by clays and sand containing foreign pebbles. This seemed to prove that the caverns, now 400 feet above Ordnance datum, must have been submerged subsequently to their occupation by the animals and by man. One of the principal objects, there-

fore, which the Committee had in view this year was to critically examine those portions of the caverns not previously explored, so as to endeavour to arrive at the true cause of the peculiar conditions observed. When the explorations were suspended last year in the Cae Gwyn Cave it was supposed that we had just reached a chamber of considerable size, but after a few days' work this year it was found that what appeared to be a chamber was a gradual widening of the cavern towards a covered entrance. The position of this entrance greatly surprised us, as hitherto we had believed that we were gradually getting further into the limestone hill. The rise in the field at this point, however, proved to be composed of a considerable thickness of glacial deposits heaped up against a limestone cliff. A shaft, 20 feet deep, was opened over this entrance from the field above. The beds were carefully measured by Mr. C. E. De Rance, Mr. Luxmoore, and the writer, during the prosecution of the work. Below the soil, for about 8 feet, a tolerably stiff boulder-clay, containing many ice-scratched boulders and narrow bands and pockets of sand, was found. Below this there were about 7 feet of gravel and sand, with here and there bands of red clay, having also many ice-scratched boulders. The next deposit met with was a laminated brown clay, and under this was found the bone-earth, a brown, sandy clay with small pebbles and with angular fragments of limestone, stalagmite, and stalactites. On June 28, in the presence of Mr. G. H. Morton, of Liverpool, and the writer, a small but well-worked flint-flake was dug up from the bone-earth on the south side of the entrance. Its position was about 18 inches below the lowest bed of sand. Several teeth of hyæna and reindeer, as well as fragments of bone, were also found at the same place; and at other points in the shaft teeth of rhinoceros and a fragment of a mammoth's tooth. One rhinoceros tooth was found at the extreme point examined, about 6 feet beyond and directly in front of the entrance. It seems clear that the contents of the cavern must have been washed out by marine action during the great submergence in mid-Glacial time, and that they were afterwards covered by marine sands and by an upper boulder-clay, identical in character with that found at many points in the Vale of Clwyd and in other places on the North Wales coast. The bone-earth seems to diminish in thickness rather rapidly outwards under the glacial deposits, but it was found as far out as the excavations have been made. Here the bone-earth rests directly on the limestone floor, with no local gravel between, as in the cavern. It would be interesting to know how far the cave-earth extends under the glacial deposits, but this could only be ascertained by making a deep cutting through the terrace of glacial deposits, which extends for a considerable distance in a westerly direction. The glacial deposits here are undoubtedly in an entirely undisturbed condition, and are full of smooth and well-scratched boulders, many of them being of considerable size. Among the boulders found are granites, gneiss, quartzites, flint, felsites, diorites, volcanic ash, Silurian rocks, and limestone. Silurian rocks are most abundant. It is clear that we have here rocks from northern sources, along with those from the Welsh hills, and the manner in which the limestone at the entrance to the cavern in the shaft is smoothed from the north would indicate that to be the main direction of the flow. The marine sands and gravels which rest immediately on the bone-earth are probably of the age of the Moel Tryfaen and other high-level sands, and the overlying clay with large boulders and intercalated sands may be considered of the age of the so-called upper boulder-clay of the area. The latter must evidently have been deposited by coast-ice. Whether the caverns were occupied in pre- or only in inter-Glacial times it is difficult to decide, but it is certain that they were frequented by Pleistocene animals and by man before the characteristic glacial deposits of this area were accumulated. The local gravel found in the caverns, underlying the bone earth, must have been washed in by streams at an earlier period, probably before the excavation of the rocky floor of the valley to its present depth. From the Glacial period up to the present time excavation has taken place only in the glacial deposits, which must have filled the valley up to a level considerably above the entrances to the caverns. The characteristic red boulder-clay with erratic blocks from northern sources is found in this area to a height of about 500 feet, and sands and gravels in the mountains to the south-east to an elevation of about 1400 feet. The natural conclusion therefore is that the caverns were occupied by an early Pleistocene fauna and by man anterior to the great submergence indicated by the high-level marine sands, and therefore also before the deposition of the so-called great upper boulder-clay of this area. As there is no evidence against such a view, it may even be legitimately assumed that the ossiferous remains and the flint implements are of an earlier date than any glacial deposits found in this area.

Fourth Report on the Fossil Phyllopoda of the Palæozoic Rocks, by Prof. T. R. Jones.—This report tabulates 37 species with their geological range, critical remarks being given on most species. There are 28 species of *Ceratiocaris* from beds ranging from the Carboniferous limestone to the Lower Wenlock; three doubtful forms are recorded from the Upper Llandovery and Tremadoc. The other forms referred to are *Emmelezoaris* (four species), *Physocaris vesica*, and *Xiphocaris ensis*, all from the Ludlow beds.

Report on the Volcanic Phenomena of Vesuvius and its Neighbourhood, by Dr. H. J. Johnston-Lavis.—The report gave a description of the volcanic activity of Vesuvius during the past year, illustrated by photographs. The fourth sheet of the Geological Map of Monte Somma and Vesuvius (scale 1 : 10,000) has been completed, and was exhibited at the meeting; this distinguishes in great detail the lava flows of various dates. The present year has been remarkable for the chances it affords for studying the subterranean structure of the Campi Phlegrei and the volcanic region around Naples. The great main drain which is to convey the sewage of Naples to the Gulf of Gaeta will traverse the region west of Naples on a line running nearly east and west. Five borings have been made to test the ground to be cut through, in which observations on the water-level, temperature, and presence of volcanic gases were made. A deep well is in progress at Lago Fusaro. Five other borings on or near the renowned Starza or fore-shore of Puzzuoli, on the new works of Sir W. Armstrong, Mitchell, and Co., are interesting as being within a few hundred yards of the celebrated so-called Temple of Serapis. Two are on the shore, and three at varying distances out to sea; they fully confirm the opinions generally held as to the oscillations of the ground here. The new Cumana Railway from Naples to Baia and Fusaro traverses the rocky escarpment just west of Naples. This has hitherto been supposed to be composed of a moderately uniform mass of pelagonatised basic marine tuff; but under the middle of the Corso Vitt. Emanuele and the Via Tasso the edge of a trachyte flow was traversed for over 70 metres. Much interesting information is expected from this railway, which will require a number of cuttings and tunnels, and will have to traverse the hot hill behind Baia. A deep well, in progress at Ponticelli on the outskirts of Naples, towards Vesuvius, has already been carried to a depth of over 100 metres; in the lower half of this a series of leucitic lava-streams was traversed, showing the great distances to which the old flows from Monte Somma reached, and also that either great depression of land has taken place, or that Monte Somma once formed a volcanic island. The work in hand, in addition to watching the progress of the works mentioned above, and mapping the old lava-streams, includes a careful study of the ejected blocks of Monte Somma, both chemical and microscopical, and a comparison of these rocks with those of the ancient volcanic regions of the Fassathal in the Tyrol, which they greatly resemble.

Thirteenth Report on the Erratic Blocks of England and Wales, by Rev. Dr. Crosskey.—This describes boulders near Settle and Kendal, to which the attention of the Committee has been called by Prof. T. McKenny Hughes, which are perched on pedestals of limestone striated in the direction of the main ice-flow. The boulders have preserved the rock immediately beneath from denudation. Mr. Plant gives much information upon the boulders in the valley of the Soar near Leicester recently well exposed in deep excavations. Thousands of blocks here occur in the boulder-clay; about one half are from Charnwood Forest, the remainder from the Permian sandstones and Carboniferous rocks of the Ashby coal-field, with blocks of mountain limestone brought fifteen or eighteen miles from the north-west; the rest are from the east side of the Pennine Chain, forty to fifty miles distant to the north-east. Details of various other excavations in and around Leicester were given, from which it is inferred that the Charnwood district was the centre of local ice-action. Dr. Crosskey and Mr. F. W. Martin describe a group of boulders between Shifnal and Tong, the stones consisting of rocks from the Lake district with Criffel granites which have evidently travelled together to their present position.

Report on the Erosion of the Sea-Coasts of England and Wales, by C. E. De Rance and W. Topley.—The information here given referred in part to the East Anglian coast, for which

several returns had been received. The rate and mode of erosion of the chalk cliffs at the north-west part of the Isle of Thanet is described by Mr. R. B. Grantham; in places as much as 20 feet in width of cliff has been lost in five years, but the average loss is not so much.

Capt. T. Griffiths and Mr. H. W. Williams contribute a report on the north-west coast of Pembrokeshire, where the alterations are in places important, and in all are historically interesting.

A report by Mr. K. McAlpine, on Pembrokeshire, illustrated by numerous photographs, was also laid before the meeting.

The Twelfth Report of the Committee on the Circulation of Underground Waters, by C. E. De Rance.—During the thirteen years the investigation had been going on much valuable information had been obtained; the complete dependence of the supply of underground water on the annual rainfall and the character and porosity of the strata on which the rain fell, had been completely established, varying from one inch to twelve inches of rainfall annually absorbed on each square mile; one inch of rain giving 40,000 gallons per day for each square mile of surface exposed. The great value of underground supplies had been shown during severe droughts, the dry-weather flow of the streams and rivers being wholly dependent on underground supplies issuing as deep-seated springs. Large quantities of water could be obtained by deep wells in suitable situations, as was well shown by the Birmingham Corporation supply,—the Aston well yielding 3 million gallons a day, the Witton well 2½ million gallons, King's Vale a quarter of a million gallons, Perry well 2 million gallons, Selby Oak well 1¼ million gallons, giving a total supply from wells of 9 million gallons a day, the remaining supply being from streams yielding 7½ million gallons a day; giving a total supply of 16½ million gallons, of which only 12 are required at present. Large supplies of pure artesian well waters are obtained and used at Nottingham, Liverpool, and Birkenhead. The supplies to other cities were investigated, and the recent successful borings at Stafford commented on.

Report of the Committee, consisting of Mr. John Cordeaux (Secretary), Prof. A. Newton, Mr. T. A. Harvie-Brown, Mr. William Eagle Clarke, Mr. R. M. Barrington, and Mr. A. G. More, re-appointed at Aberdeen for the Purpose of Obtaining (with the consent of the Master and Brethren of the Trinity House and the Commissioners of Northern and Irish Lights) Observations on the Migration of Birds at Lighthouses and Light-vessels, and of reporting on the same.—The General Report of the Committee, of which this is an abstract, is comprised in a pamphlet of 173 pages,[1] and includes observations taken at lighthouses and light-vessels, as well as at several land stations, on the coasts of Great Britain and Ireland and the outlying islands. The best thanks of the Committee are due to their numerous observers for their assistance. Much good work has been rendered by those amongst them who have taken the trouble to forward a leg and wing of such specimens as have been killed against the lanterns, and which they have themselves not been able to identify. This has already led to the determination of several rare birds, which otherwise would have escaped notice. It is evident that, unless the birds can be correctly named, the value of this inquiry is materially diminished, and ornithologists may justly refuse to accept the accuracy of the statements. It is intended, in order to facilitate the sending of wings, to supply the light-keepers with large linen-lined envelopes, ready stamped, and inclosing labels for dates and other particulars. The best thanks of the Committee are also tendered to Mr. H. Gätke for the increased interest he has given to their Report by forwarding a daily record of the migration of birds as observed at Heligoland between January 1 and December 31, with the concurrent meteorological conditions under which the various phenomena occurred. Altogether 187 stations were supplied with printed schedules for registering the observations, and returns have been sent in from 125. About 267 separate schedules have been sent in to your reporters. The general results, as far as the special object of the inquiry, have been very satisfactory, and much information has also been accumulated respecting the breeding habits of sea-fowl on the outlying islands and skerries on the Scotch and Irish coasts, and altogether a great mass of facts and valuable data obtained which cannot fail to be of value to future inquirers. A special point of interest in the Report is the large arrival, with a north-east wind, of pied flycatchers in the first week in May 1885, observed at Spurn Point, Flamborough Head, the Isle of May, and Pentland Skerries. At Flamborough Head the flycatchers were accompanied by male redstarts in large numbers, both species swarming for two or three days. The immigration at this period was not exclusively confined to these two species. Mr. Agnew, writing from the Isle of May, at the entrance of the Firth of Forth, says, under date of May 3:—"An extraordinary rush of migrants to-day; have never seen anything like it in spring. To attempt to give numbers is simply useless. I will just give you the names in succession: fieldfares, redwings, ring-ouzels, blackbirds, lapwings, dotterels, rock-pigeons, hawk, meadow pipits, redstarts, whinchats, tree-sparrows, yellow wagtails, ortolan (obtained), robins, chiff-chaffs, wood-warbler, blackcap warbler, marsh-tit, whitethroats, and pied flycatchers." And on the 4th: "Stil increasing in numbers, but wind shifted this morning to E. for S.E." A noteworthy incident also of the vernal migration was the great rush of wheatears observed at the Bahama Bank vessel off the Isle of Man, and at Langness on the night of April 13, when many perished and were captured. On the same night, wheatears were killed at the Coningbeg and Rathlin Island Lighthouses on the Irish coast. On the 12th and 13th the rush was very heavy at stations on the west coast of Scotland. No corresponding movement was observed on the east coast of Great Britain on the same night; but at Hanois L.H., Guernsey, on May 10, at night at the north light, and on the Lincolnshire coast and Farn Islands on the 10th and 11th. These entries are sufficient to show the immense area covered by the migration of this species at or about the same period. On the east coast of England the first wheatears were observed at the Farn Islands on February 22. The autumnal migration is first indicated at Heligoland on July 6, and was continued with slight intermissions up to the end of the year. A similar movement affected the whole of the east coast of Great Britain during the same period, but was apparently less constant and persistent than at Heligoland. It has been remarked in previous Reports that the migration of a species extends over many weeks, and in some cases is extended for months. Yet it is observable that, at least on the east coast of England, year by year, the bulk or main body of the birds come in two enormous and almost continuous rushes during the second and third weeks in October and the corresponding weeks in November. In the autumn of 1885 it is again observable that the chief general movements which usually characterise the southward autumnal passage were two in number, and affected the stations over the whole coast-line both east and west of Great Britain. The first of these commenced about October 11, and was continued to the 20th. The second from November 8 to 12. It is worthy of notice that these two chief movements of the autumn were ushered in by, and concurrent with, anti-cyclonic conditions, preceded by, and ceasing with, cyclonic depressions, affecting, more or less, the whole of the British Isles. From this it appears not unlikely that birds await the approach of favourable meteorological conditions, of which, perhaps, their more acute senses give them timely warning, to migrate in mass. Whatever may be the cause which impels these enormous rushes, often continuous for days, it is one which operates over an immense area at one and the same time. The October rush reached its maximum on the 16th, at which date almost all the stations report extraordinary numbers of various species on the wing. As one out of many, we quote from the journal of Mr. James Jack, principal of the Bell Rock Lighthouse:—"Birds began to arrive at 7.30 p.m., striking lightly and flying off again; numbers went on increasing till midnight, when it seemed that a vast flock had arrived, as they now swarmed in the rays of light, and, striking hard, fell dead on balcony or rebounded into the sea. At 3 a.m. another flock seemed to have arrived, as the numbers now increased in density; at the same time all kinds crowded on to the lantern windows, trying to force their way to the light. The noise they made shrieking and battering the windows baffles description. The birds were now apparently in thousands; nothing ever seen here like it by us keepers. Wherever there was a light visible in the building they tried to force their way to it. The bedroom windows being open as usual for air all night, they got in and put the lights out. All birds went off at 6 a.m., going W.S.W. Redwings were most in number, starlings next, blackbirds, fieldfares, and larks." The rush in November chiefly took place in the night; at the Bell Rock the movement ceased at midnight of the 12th, and at

[1] "Report on the Migration of Birds in the Spring and Autumn of 1885." (McFarlane and Erskine, 19, St. James's Square, Edinburgh.)

the Longstone Lighthouse, on the Farn Islands, a little earlier—at 10.30 p.m., when the wind became strong from S.W. From each succeeding year's statistics we have come to almost similar conclusions regarding the lines of flight—regular and periodically used routes where the migratory hosts are focused into solid streams. Three salient lines on the east coast of Scotland are invariably shown, viz. (1) by the entrance of the Firth of Forth, and as far north as Bell Rock, both coming in autumn and leaving in spring; (2) by the Pentland Firth and Pentland Skerries, likewise in spring and autumn; and (3) by the insular groups of Orkney and Shetland, which perhaps may be looked upon as part of No. 2. On the other hand, three great areas of coast-line, including many favourably lighted stations, almost invariably, save in occasionally protracted easterly winds, and even then but rarely, send in no returns, or schedules of the very scantiest description. These areas are Berwickshire, the whole of the east coast south of the Moray Firth, and Caithness and East Sutherland. Each and all of these areas possess high and precipitous coast-lines, if we except the minor estuaries of the Rivers Tay and Dee, and a small portion of the lower coast-line of Sutherland, which face towards the east. On the east coast of England these highways are less clearly demonstrated. The Farn Islands, Flamborough Head, and the Spurn are well established points of arrival and departure; but south of the Humber as far as the South Foreland the stream appears continuous along the whole coast-line, and to no single locality can any certain and definite route be assigned. It cannot be said that the southerly flow of autumn migrants is equally distributed along the entire west coast of England. On the contrary, the schedules afford unmistakable evidence that the great majority of these migrants, so far as the English and Welsh coasts are concerned, are observed at stations south of Anglesey. But while the north-west section of the coast is thus less favoured than the rest, such is not the case with the Isle of Man, which comes in for an important share of the west coast migratory movement. The fact has already been alluded to that large masses of immigrants from Southern Europe pass through the Pentland Firth, and, along with migrants from Faroe, Iceland, and Greenland, pass down the west coast of Scotland, whence many cross to Ireland, and it seems most probable that the remainder leave Scotland at some point on the Wigtown coast, and pass by way of the Isle of Man to the west coast of Wales, and thus avoid the English shore of the Irish Sea. The schedules sent in from the coasts of Flint, Cheshire, Lancashire, and Cumberland show that in 1884–85 comparatively few migrants were observed, and that the great general movement did not affect them in any general degree. These remarks do not apply to migrants amongst the waders and ducks and geese, which, as a rule, closely follow coast-lines, and which are abundantly represented on the Solway and coasts of Cumberland and Lancashire. There is a much-used bird route along the north coast of the British Channel, and thence, from the Pembroke coast, across to Wexford, passing the Tuskar Rock, the best Irish station. The fact of a double migration or passage of birds, identical in species, across the North Sea in the spring and autumn both towards the E. and S.E., and to the W. and N.W., is again very clearly shown in the present report. This phenomenon of a cross migration to and from the Continent, proceeding at one and the same time, is regularly recorded on the whole of the east coast of England, but is specially observable at those light-vessels which are stationed in the south-east district; at the same time, it is invariably persistent, and regular year by year. Our most interesting stations are those on small islands or rocks, or light-vessels at a considerable distance from shore, and the regular occurrence of so many land birds, apparently of weak power of flight, around these lanterns, is a matter of surprise to those unacquainted with the facts of migration. No clear indication of the migration of the redbreast has yet been shown on the Irish coast; the records of its occurrences are few and scattered. The black redstart was recorded at several stations in the southern half of Ireland; specimens were forwarded from Mine Head, the Skelligs, and Rockabill. It is apparently a regular winter visitant to the Skelligs and Tearaght, generally appearing in October and November. The occurrences so far recorded by the Committee of the black redstart on the east coast of Great Britain, in the autumn, range between October 23 and November 3. In the spring of the present year, Mr. G. Hunt, under date of March 20, reports an extraordinary flight of rooks at Somerton, on the Norfolk coast, which he observed from 10.30 a.m. to 6 p.m. He says:—"I observed them flying just above the sand-hills, going due south, and as far as the eye could see both before and behind there was nothing but rooks. There could never for one moment in the day be less than a thousand in sight at one time; they kept in a thin wavering line. The coast line here runs due north and south." Mr. J. H. Gurney reports:—"I saw the rooks and grey crows on the same day in much smaller numbers as were seen at Somerton, which is fifteen miles further south. I again saw them on the 21st, 22nd, 25th, 26th, and 29th, but none after this date; with us, however, grey crows preponderated; the direction was to S.E. An enormous migration of these and many others is recorded from Heligoland, also from Hanover between March 19 and 25." In conclusion your Committee wish to thank H.R.H. the Master and the Elder Brethren of the Trinity House, the Commissioners of Northern Lights, and the Commissioners of Irish Lights for their ready co-operation and assistance, through their intelligent officers and men, in this inquiry. The Committee respectfully request their re-appointment.

Report of the Committee, consisting of Prof. Cleland, Prof. McKendrick, Prof. Ewart, Prof. Stirling, Prof. Bower, Dr. Cleghorn, and Prof. McIntosh (Secretary), for the Purpose of continuing the Researches on Food-Fishes and Invertebrates at the St. Andrews Marine Laboratory.—The Committee beg to report that the sum of 75*l.*, placed at their disposal, has for the most part been expended in the purchase of instruments and books permanently useful in the Laboratory, only a limited proportion having been disbursed for skilled assistance. Since the meeting of the Association at Aberdeen last year several structural improvements in the wooden hospital, now converted into the Laboratory, have been completed, and others are being carried out by the Fishery Board for Scotland. These changes will render the temporary building much more suitable for work. A small yawl of about 21 feet in length has also been added to the apparatus by the Fishery Board. The desiderata now are an increase in the number of good microscopes and other expensive instruments, and an addition to the nucleus of books which workers require always at hand. In this respect the Laboratory has been much indebted to the Earl of Dalhousie, who forwarded a complete set of Fishery Blue-Books, and to the Trustees of the British Museum, who sent such of their publications as bore on marine zoology. Collections of papers have also been forwarded by many observers, amongst whom Prof. Flower, the late Dr. Gwyn Jeffreys, and Prof. Alexander Agassiz are conspicuous. Most of the Continental and American workers in marine zoology and cognate subjects, as well as those of our own country, are indeed represented. The first work of the year was the examination of a fine male tunny, 9 feet in length, caught in a beam-trawl net near the mouth of the Forth, and the skeleton of which is now being prepared for the University Museum. Various interesting anatomical features came under notice, and its perfect condition enabled a more correct figure of its external appearance to be made (*vide Ann. Nat. Hist.*, April and May 1886, and "Fourth Report of the Fishery Board for Scotland," plate 8). The examination of various food- and other fishes in their adult and young conditions was systematically carried out, and notes on the following species will be found in the *Annals of Natural History*, and the "Report of the Fishery Board":—Weever (greater and lesser), shanny, sand-eel, halibut, salmon, common trout, herring, sprat, conger, ballan-wrasse, shagreen-ray, piked dog-fish, and porbeagle-shark. Special attention was also given to the "Mode of Capture of Food-Fishes by Liners," "Injuries to Baited Hooks and to Fishes on the Lines," "Shrimp-Trawling in the Thames," "Sprat-Fishing," and to the "Eggs and Young of Food- and other Fishes," "Diseases of Fishes," the "Effect of Storms on the Marine Fauna," and "Remarks on Invertebrates, including Forms used as Bait" (*vide* "Fourth Report of the Fishery Board for Scotland," 1886). The active work in connection with the development of fishes for the season may be dated from the middle of January, when one of the local trawlers captured a large mass of the ova of one of the food-fishes, viz. the catfish. The embryos in these eggs (which are the size of the salmon's) were well advanced, so that, with the exception of a few unimpregnated ova observed during the trawling experiments of 1884, the earlier stages have yet to be examined. The large size of the embryos of the catfish permitted a satisfactory comparison to be instituted between them

and the salmon, which had formerly been under examination, and the results, with drawings of both forms, are nearly completed, and will be communicated to one of the Societies during the winter. The first pelagic ova, viz. those of the haddock, made their appearance during the very cold weather in the beginning of February, and the examination of these, together with those of the cod and common flounder—both of which were unusually late—enabled Mr. E. E. Prince and the Secretary to extend considerably the observations of last year. Moreover, for the first time, the ova of the ling (*Molva vulgaris*) were examined, and the development followed to a fairly advanced stage. These were procured by a long-line fisherman of Cellardyke (who with others was supplied with suitable earthenware jars[1] and encouraged by a visit to the Laboratory), fertilised about 100 miles off the Island of May, and safely brought, after a considerable land journey, to St. Andrews. The fertilised ova of the plaice and lemon-dab were similarly brought by Capt. Burn, late of the Hussars, from the Moray Frith; for the Laboratory had then no boat suited for procuring a supply nearer home. No fish, however, has been more useful to the workers this season than the gurnard (*Trigla gurnardus*), the spawning period of which seems to have been somewhat later than usual. The first ova were procured about the middle of May, and the embryos of the last hatching (middle of August) still swarm in the vessels. Further observations were also made on the ova and young of the lumpsucker, Montagu's sucker, shanny, stickleback, sand-eel, *Cottus*, &c. Amongst others the ripe ovum of *Ammodytes tobianus* has been examined. It is colourless, translucent, and has a beautifully reticulated capsule. Mr. Prince is of opinion that, as suggested in the "Report of H.M. Trawling Commission," it most nearly resembles a pelagic egg. Moreover, the information necessary for filling up the gaps between the very early stages of the young food-fishes near the surface and their appearance off the shore as shoals of young forms more or less easily recognisable specifically has been considerably increased. Much of this knowledge has been obtained by the aid of a huge tow-net of coarse gauze—upwards of twenty feet in length—attached to a triangle of wood, ten feet each way, sunk by a heavy weight and kept steadily at the required depth in fathoms by a galvanised iron float, such as is used for the ends of herring-nets. Since the completion of the net, however, the services of the Fishery Board tender *Garland* have only once been available, and the yawl has been at our disposal only a few weeks. In these brief opportunities, however, the young of various fishes have been obtained at stages hitherto unknown, and some rare invertebrates and a new Medusa have been captured. Enough, in short, has been seen to indicate the value of this apparatus, and of certain modifications of the ordinary beam-trawl for work on the bottom. The hatching and rearing of the embryos of the common food-fishes have been attended with much greater success than last year or the previous one, and a large series of microscopic preparations (chiefly sections with the Caldwell and rocking microtomes) has been made by Mr. E. E. Prince, embracing the entire development of the food-fishes from the early ovum to a late larval stage. The study of these preparations is now being proceeded with; but in traversing a field so extensive as the embryology of these important Teleosteans a great expenditure of time and labour is required. It is hoped, however, that the results will be completed during the winter (*vide* for other observations the *Annals of Natural History* for April, May, June, and August 1886; NATURE, June 1886, &c.). Since the beginning of June, Dr. Scharff has been occupied with the investigation of the intra-ovarian egg of a number of Teleostean fishes. Among the ovaries examined were those of *Trigla gurnardus*, *Gadus virens* and *G. luscus*, *Gadus merlangus*, *Anarrhichas lupus*, *Conger vulgaris*, *Blennius pholis*, *Lophius piscatorius*, and *Salmo salar*. The researches were made on fresh ovaries and on spirit specimens. Most of those reserved for section-cutting were previously treated either with picro-sulphuric or weak chromic acid. Special attention was paid to the structural changes in the growing nucleus. The origin of the follicular layer surrounding the egg, as well as the origin and development of the yolk, will be dealt with in a paper to be published shortly. Considerable advancement has been made in the study of the development of the common mussel by Mr. John Wilson. Some of the very early larvæ are described in the report of last year, along with an account of the artificial methods employed. This year embryos were developed for forty days in vessels suitable for microscopic manipulation. Normal growth continued during the first fourteen days. At the end of this period the largest embryos had shell-valves ·128 mm. in length. They are transparent and almost semicircular, the dorsal (hinge-) line being nearly straight. The powerful velum could be wholly withdrawn within the valves. The alimentary system was conspicuously developed. In the beginning of June great numbers of young mussels were found swimming actively on the very surface of the sea close to the shore, and measuring ·134 mm. They differed from the most advanced of those artificially reared only in their being more robust, the stage reached being the same in both. At various periods somewhat later in the season many older, though still microscopic, mussels were captured with the tow-net in St. Andrews Bay from the shore seaward for 4 miles. Besides the careful study of their development, Mr. Wilson has also been engaged with the histology of the mussel (especially that of the generative organs) at various stages, up to the adult condition. The Committee beg to recommend a renewal of the grant (100*l.*) for the ensuing year.

[1] Containing about a gallon. These were partially filled with pure sea-water containing the fertilised ova, and simply tied over with porous cheese-cloth.

Report of the Committee, consisting of Prof. McKendrick, Prof. Struthers, Prof. Young, Prof. McIntosh, Prof. Alleyne Nicholson, Prof. Cossar Ewart, and Mr. John Murray (Secretary), appointed for the Purpose of Promoting the Establishment of a Marine Biological Station at Granton, Scotland.—The Committee report that the sum of 75*l.*, placed at their disposal, has been used to aid in defraying the expenses of carrying on the work of the Scottish Marine Station at Granton. Two reports on the work of the institution during the past year are given below; they have been sent in to the Secretary by Mr. J. T. Cunningham, the Superintendent, who has charge of the zoological investigations; and Dr. Hugh Robert Mill, who is responsible for the physical work:—

The biological work of the Station falls into three principal divisions: (1) Embryology and morphology; (2) faunology; (3) the accommodation of students and investigators. (1) Efforts to elucidate some facts bearing on the reproduction and development of Myxine formed the principal part of the work under this head during the autumn and winter. In the summer the aquarium had been arranged, and a large tank was specially devoted to the purpose of keeping specimens of the animal in confinement. After careful attention to the matter, it was found that the creatures refused entirely to feed while in captivity; they lived several months, but no signs of reproductive activity appeared, with one exception noted below. It was then determined to continue the examination of large numbers of specimens every month in the year in order to find if the ova were shed at any limited season. As almost nothing accurate was known on the whole subject, the first problem was to obtain ripe males and females. In November the testis in its immature condition was recognised, and it was subsequently found that with few exceptions all very immature specimens were hermaphrodite, containing immature testicular tissue at the posterior end of the generative organ. Microscopic examination of the largest ova obtained showed that the well-known polar threads belonged to the vitelline membrane, and were developed in tubular depressions of the follicular epithelium. In December, January, February, and March, females were obtained which had just discharged their ova, the collapsed capsules, still quite large, being present in the ovary. At the end of January two females were obtained in which the polar threads were so far developed as to form projections at the ends of the inclosing follicle. One specimen with eggs in this condition was taken from the aquarium. No perfectly ripe ova were ever obtained. In February moving spermatozoa were discovered in hermaphrodite specimens, but the total quantity of milt present was quite insignificant. The greater number of the specimens examined were obtained from fishermen's lines baited for haddock; some were taken by baited traps. In March dredging was carried on off St. Abb's Head, with a view to obtain deposited fertilised eggs of Myxine, but none were found. It has thus been shown that Myxine deposits its eggs in the months of December to March, and that the females are taken on the hook immediately after the eggs have been shed. But no method has been discovered of obtaining adults in the ripe condition, or of obtaining the fertilised ova and embryos. The research and its results are described in a paper in the *Proceedings* of the Royal Society of Edin-

burgh, and more fully in a paper which will appear in the next number of the *Quarterly Journal of Microscopical Science*. At the beginning of the present year the systematic examination of the ova of all species of fish which could be obtained was commenced. The pelagic ova of the cod, haddock, whiting, and gurnard had been examined in the previous spring, and those of a large number of additional species have now been figured and described at successive stages of development. The results of this work are now being published in full by the Royal Society of Edinburgh, and will appear as a memoir in the Society's *Transactions*. (2) The faunological investigations have been carried on as time permitted since the opening of the Station, and have, since June last, been receiving particular attention. A Report on the Chætopoda, in the preparation of which Mr. G. A. Ramage is giving his assistance, will appear in the coming autumn; a Report on the Sponges is being prepared by Mr. J. Arthur Thomson; and miscellaneous notes on other classes will be incorporated with these special Reports. (3) The following is a list of those who have carried on studies at the Station:—

	Name	Began	Left	Subjects
1885.	Dr. Kelso, Edinburgh ...	Aug.	Sept. 26	Teleostean ova
	And. D. Sloan, Edinburgh	Aug. 8	April 1886	Cœlenterates

The yacht is kept up in the same condition as at the opening of the Station, and the number of men is unaltered. The ark at Millport is again in use this summer, and is in the charge of Mr. David Robertson. Mr. Cunningham worked there for one week in June, having found at Millport a particularly favourable opportunity for the study of Teleostean ova. Many other naturalists have taken part in the *Medusa's* dredgings in the Clyde district during the present summer. The services of Alex. Turbyne, the keeper of the Station, in making excursions in trawlers to procure fish ova, have been most valuable. All those interested in the Station are greatly indebted to Mr. Robert Irvine, of Royston, for the friendly assistance which he has always been ready to afford on every occasion. Preserved specimens of marine animals and plants are still sent out to applicants, and some attention is being paid to the question of oyster-cultivation in the Firth of Forth.

J. T. CUNNINGHAM, B.A., F.R.S.E.

Physical marine research has, from the commencement, formed one of the distinctive features of the Scottish Marine Station. During last year work has been carried on in this direction by Dr. H. R. Mill and Mr. J. T. Morrison; other gentlemen have occasionally made use of the facilities of the Station. Regular meteorological observations are continued twice daily, and include the temperature at surface and bottom of the water. An elaborate set of experiments with Mr. John Aitken's new forms of thermometer-screen were completed last year by Mr. H. N. Dickson, who has discussed the results in connection with those obtained by him with the same apparatus on Ben Nevis. Experiments with various anemometers are still in progress. Atmospheric dust is being collected on several islands in the Firth of Forth, by means of large funnels and carboys, which are periodically emptied and the contents forwarded to Mr. Murray for examination. Monthly trips along the Firth of Forth for the observation of temperature and salinity have taken place regularly from river to sea; preliminary results have been communicated to the Royal Society of Edinburgh from time to time, and a complete discussion of salinity is nearly ready for publication. It shows remarkable relationships between salinity and configuration, which have suggested new definitions of the words *river*, *estuary*, and *firth*. Special attention has been devoted to the relation of salinity and temperature to tide in the estuary of the Forth. Besides the observations of the scientific staff of the Station, thermometer readings are taken by volunteer observers at different parts of the Forth river-system and in the adjacent parts of the North Sea. The *Medusa* has made regular trips on the Clyde since April last at intervals of two months. Temperature and salinity observations are made in all parts of the estuary and firth from Dumbarton to the North Channel, and in all the connected lochs. These trips have yielded results of great interest and novelty. They are communicated in several papers to various Sections of the present meeting. The temperature of two deep fresh-water lakes—Loch Lomond and Loch Katrine—has been observed at all depths once a month since November 1885, in continuation of Mr. J. Y. Buchanan's work. Daily temperature observations have been established on a number of rivers and at several points on some. The Station has charge of observations on the Thurso, in the north of Scotland, the Forth and Teith, and the Tweed; and it has also been the means of inducing independent observers to undertake similar work on the Tummel (a tributary of the Tay), the Tay, and the Derwent, in Cumberland. These are all salmon rivers, and the observers being interested in fishing have already succeeded in showing some connection between temperature and the movements of salmon. In consequence of experience gained in physical marine investigations the apparatus used for the purpose has been progressively modified and improved—the Scottish thermometer-frame and water-bottle may be pointed to as special instances. The Station has, since September 1885, been able to advise and assist several public bodies in starting observations of temperature and salinity, the National Fish Culture Association of England, the Dundee Harbour Trust, and the Fishery Board for Scotland being amongst the number. Thermometers have been lent to several naturalists for use on short scientific voyages. The collection of all existing records of sea and river temperature round the coast of Scotland is proceeding, and promises, when completed, to be of great value in showing the different sea-climates of the east and west coasts—a question of much importance in relation to the distribution of marine species.

HUGH ROBERT MILL, D.SC., F.R.S.E.

Report upon the Depth of Permanently Frozen Soil in the Polar Regions, its Geographical Limits and Relations to the Present Poles of Greatest Cold, by a Committee consisting of Lieut.-General J. T. Walker, C.B., F.R.S., General Sir J. H. Lefroy (Reporter), Prof. Sir W. Thomson, Mr. Alex. Buchan, Mr. J. Y. Buchanan, Mr. John Murray, Dr. J. Rae, Mr. H. W. Bates (Secretary), Capt. W. J. Dawson, R.A., Dr. A. Selwyn, and Prof. C. Carpmael.—The inquiry referred to the Committee necessitated reference to residents in many distant regions, and time must elapse before any large harvest of observations can be hoped for; nevertheless, the Committee are in a position to quote several valuable communications, especially one from Mr. Andrew Flett, adding materially to what was previously known on the subject of the extension of permanently frozen soil, or ground ice, in America. It will be convenient to arrange the data now available, in their order of latitude.

1. Lat. 71° 18′ N., long. 156° 24′ W.—At the wintering station of the United States Expedition of 1881-82, under Lieut. P. H. Ray, United States America, that officer found the temperature of the soil 12° F. at 28 feet from the surface, and the same at 38 feet.

2. Lat. 68° N., long. 135° W.—At Fort Macpherson, on Peel River, Mr. Andrew Flett, who passed twelve years there, reports:—"The greatest depth of thawed-out earth I came across round that post was 3½ feet, October 10, 1865. The greatest depth of frozen ground was 52 feet 3 inches, September 27, 1867, near the mouth of Peel River. The bank had fallen in; at the bottom the perpendicular cliff, which I tried with a boat pole, was frozen as hard as a rock. A black sandy soil. The surface was not above two feet thawed-out. The cliff was measured with the tracking line." This account leaves it doubtful whether the frost may not have entered the soil from the face of the cliff. On the other hand it is evident that it extended to a greater depth from the surface than was measured.

3. Lat. 67° N., long. 142° W., on the Youcon.—The same gentleman writes:—"I spent twelve years on the Pelly or Youcon River, on the west side of the Rocky Mountains. Round old Fort Youcon ground ice is found at 6 feet; this I have seen in the river banks in September where they had caved in; but no particular notice has been taken as far as I know by any one, unless it be Chief Factor Robert Campbell, now residing in Merchiston, Strathclair, P.O., Manitoba."

4. Lat. 65° N., long. 120° W., on the Mackenzie River, about ten miles above the mouth of Bear River.—The same gentleman writes:—"I have seen many landslips on the Mackenzie, which

more frequently takes place in rainy weather—July, August, and sometimes September: but I never examined them particularly excepting one, which we came near being buried by in camp. This was about August 15, 1876. By a pole, I found the bottom of the slide frozen hard, a grey clay and gravel mixed, *from where the earth broke off was not over 6 feet.* The surface soil sandy. Some way back from the river bank the country is muskeg more or less, and by removing the moss by hand we came to hard frozen ground in August." The sentence printed in *italic* is somewhat ambiguous. It is understood to mean that the bank was not much more than 6 feet high, and was hard frozen at that depth; the depth to which the frost extended is therefore unknown.

5. Lat. 64° 20′ N., long. 124° 15′ W., on Mackenzie River. —The face of a cliff from which a recent land-slide had occurred, was measured by the present reporter in June 1844. The soil was frozen to a depth of 45 feet from the surface. (*See* "Magnetic Survey," p. 161.)

6. Lat. 62° 39′ N., long. 115° 44′ W., at Fort Rae, on Great Slave Lake.—Capt. Dawson, R.A., observed the temperature of the soil monthly at his station of circumpolar observation, 1882–83. The following table contains his results in degrees Fahr.:—

Months	1 Foot	2 Feet	3 Feet	4 Feet
1882	°	°	°	°
September	40·6	37·9	36·1	34·5
October	32·5	32·7	32·5	32·3
November	23·9	29·1	30·9	31·3
December	15·8	24·6	28·8	30·8
1883				
January	8·3	19·9	25·7	28·5
February	11·1	21·2	24·5	26·3
March	9·5	20·8	22·7	24·8
April	18·9	25·2	24·3	25·3
May	34·0	32·0	33·8	30·5
June	43·5	36·5	32·4	31·5
July	48·0	41·0	37·0	34·5
August	47·3	41·9	38·5	36·5

The mean temperature of the air at 5 feet 10 inches above the surface, in the same months, was as follows:—

1882		1883	
September	44·40°	February	−10·41°
October	32·59	March	−7·71
November	9·30	April	19·30
December	−15·20	May	36·30
		June	51·49
1883		July	61·11
January	−26·80	August	56·50

We learn from this table that the soil is frozen at a depth of 4 feet from November to June inclusive, and is at the lowest temperature at that depth in March. It further shows that, like the waters of the Scottish lakes, as proved by the observations of Mr. J. Y. Buchanan and Mr. J. F. Morrison in Loch Lomond and Loch Katrine last winter, the mean temperature of the soil reaches its minimum about the time of the vernal equinox. The rise of earth-temperature in February above that recorded in either January or March is remarkable. It does not appear, from the conver ence of the lines when projected, that temperatures below 32° F. extend lower than 11 or 12 feet. Capt. Dawson writes:—"There are two reasons why these earth-temperatures are above what is probably the average in that latitude. (1) The ground had a slope of 1/16 to the south-west; and (2) it was fully exposed to the rays of the sun; now, in most places, the ground is either covered with thick moss or shaded by brushwood, and its surface-temperature on the hottest day is not likely to exceed 70° F., whereas earth exposed to the rays of the sun may easily reach a temperature of 120° F." Fort Rae is situated on a long arm or inlet of Great Slave, baving a depth of 10 or 12 feet of water.

7. Lat. 62°, long. 129° 40′, Jakutsk, Siberia.—The great depth of permanently frozen soil in this part of the valley of the Lena has long been well known; but the following extract, translated from a recent paper by Dr. Alex. Woeikof, of St. Petersburg, entitled "Klima von Ost-Siberien," contains infomation on the influence of local conditions which will make it of value to observers, and we therefore reproduce it.

"The further north," he remarks, "the longer is the duration of cold in valleys in comparison with that on higher ground. The effect extends to a part of autumn and spring, and is observable in the mean temperature of the year."

The following observations of earth-temperatures are a proof:—

	At Depth				Limit of
	20 ft.	50 ft.	300 ft.	381 ft.	Frozen Soil
Jakutsk[1]	13°·6	17°·1	25°·0	26°·6 Fahr.	620 feet.
Mangan mine	22°·1	25°·2	...	...	269 ,,
Schelou mine	22°·1	25°·7	...	...	298 ,,

Thus, on heights in the vicinity of Jakutsk (these are heights on the left bank of the Lena, near Jakutsk) the earth temperature is from 8°·1 to 8°·6 F. higher than it is in the town and valley at the same depth, and it is even lower at 300 feet in the former than at 50 feet in the latter locality. The total depth of frozen soil is, according to Mittendorf ("Sibirische Reise," Bd. i.) more than twice as great in the valley as it is on the heights: and observe that these lesser heights are in winter relatively colder than higher isolated mountains. Mittendorf also states that no frozen soil was found at 60 metres above the level of the river at the mouth of the Maja, in Aldan, but that it was found four miles and a quarter up the stream at three metres above the level of the river, and that about 28 miles further, in the mountains, there is a deep hollow from which aqueous vapour is constantly rising.

Kuppfer asserts that in Bergrivier Nertschinsk, in the Trech Swjatitilei mine, frozen soil was found at a depth of 174 feet, but that in Wossdwischenst mine, which lies 230 feet higher, the frozen soil ceased at 50 feet. Even in Altai it is acknowledged that many valleys are colder than the neighbouring heights.

Dr. Woeikof sums up a number of observations in the following sentences, which apply to the greater part of East Siberia, but more particularly to the north-east portion.

(1) As the greater cold coincides with calms and light winds, the valleys and lower grounds are colder than the heights.

(2) The temperature of isolated mountains is relatively higher than that of lesser elevations.

(3) The lowering of temperature in the valleys is so lasting and considerable that the mean of the year is also lowered, as is proved by the observations of earth-temperature.

(4) The depth of the frozen soil is greater in valleys than on the neighbouring heights, probably also than it is on the higher mountains.

(5) In the tundras of the far north (answering to the barren grounds and muskegs of the North-West Territory of Canada), the winter is warmer than in the valleys of the forest-zone. Probably because the stronger currents of the air do not permit the cold stratum to remain so long stagnant.

8. Lat. 61° 51′, long. 125° 25′, Fort Simpson, on Mackenzie River.—The summer's heat was found in October 1837 to have thawed the soil to a depth of 11 feet, below which was 6 feet of ground ice (Richardson), making the depth of descent of the frost 17 feet. The result is anomalous; at other posts in the same region the summer thaw is much more superficial. Thus, it will be observed above, that in the month of October, at Fort Rae, the soil was at a nearly uniform temperature, but slightly above the freezing-point, from the depth of 1 foot to 4 feet. Franklin found a summer thaw of only 22 inches at Great Bear Lake, and the writer was informed that it was only 14 inches at Fort Norman (lat. 64° 41′). Fort Simpson is situated on an island of deep alluvial soil, bearing timber of large size, and possessing an exceptional climate.

9. Lat. 57°, long. 92° 26′, York Factory, Hudson's Bay.—Sir J. Richardson has stated that the soil was found frozen to a depth of 19 feet 10 inches in October 1835, the surface being thawed to a depth of 2 feet 4 inches.

10. Lat. 55° 57′, long. 107° 24′, Lake à la Crosse.—It is stated that no frozen soil was found in sinking a pit to a depth of 25 feet in 1837, and that the earth was only frozen to a depth of 3 feet in the winter of 1841. Both records are anomalous, and call for verification.

11. Lat. 53° 40′, long. 113° 35′, at Prince Albert, on the Saskatchawan.—Mr. W. E. Traill, who was in charge of this post in 1872, reports that a settler in the neighbourhood came to frozen ground at a depth of 17 feet, but did not learn whether they passed through the frozen strata, or, if such was the case,

[1] M. Schergin's shaft.

what was the thickness of it. The same gentleman, writing from Lesser Slave Lake (lat. 55° 33′), remarks that he has never come across any indication of perpetual ice during the twenty-two years he has passed in the North-West Territory.

12. Mr. Andrew Flett, writing from Prince Albert, April 21, 1886, says:—"Hundreds of wells have been sunk in this settlement; one I had sunk myself, beginning of July 1881, 27 feet deep—saw no frozen earth. As far as I have noticed on this prairie land, when there is a good fall of snow when the winter sets in, the frost does not penetrate so deep as when there is no snow till late, and in some years very light snow. I had a pit opened on the 9th inst. (April); the surface was thawed 3 inches; we got through the frozen earth at 4 feet 7 inches. On the 11th inst. I saw a grave dug in the churchyard at Emmanuel College, one mile from my place, 5 feet deep, and had not got through the frost. My place is on higher ground, loam soil."

13. Mr. W. Ramsay, settled on the South Saskatchawan, thirty-five miles from here, sunk a well 40 feet, May 27, 1884—no frost.

14. Mr. Jos. Finlayson, three miles from here, sunk a well beginning of July 1882, 46 feet. He saw no frost.

15. Mr. J. D. Mackay, on the same section as the above, sunk a well 27 feet, July 15, 1884, found particles of frozen earth at 7 feet deep.

16. Mr. W. C. Mackay, my next neighbour half a mile west of this, sunk a well about June 20, 1884, found particles of frozen earth at $5\frac{1}{2}$ feet.

17. Lat. 53° 32′, long. 113° 30′, Fort Edmonton, on the Saskatchawan, 2400 feet above the sea.—Dr. James Hector, on March 5, 1858, found the soil frozen to a depth of 7 feet 6 inches (*Journal R. G. S.* vol. xxx. p. 277).

18. Lat. 51° 14′, long. 102° 24′.—At Yorkton, Mr. J Riaman, when digging a well last summer (1885), found the frost at a depth of 19 and 20 feet, and continuing for a depth of 30 inches. In this case, therefore, the total depth to which frost descended was about 22 feet. Mr. J. Tarbotton, of Yorkton, in communicating the last observation, remarks:—"The depth to which frost penetrates during the winter, varies, I find, with the character of the winter itself and with the nature of the locality. I made observations in an open unprotected spot, where there was little or no snow, and found frost to the depth of 5 feet 9 inches. This occurred last July, and the frost was then about 2 feet deep (*i.e.* had descended to 7 feet 9 inches). But in the bluffs near my house, I dug a cellar, at the same time, going down between 8 and 9 feet, encountering no frost at all.

"This year, however, when digging another well in April, in almost the same place, I encountered frost at 2 feet, and the ground continued solid until I had gone down from $4\frac{1}{2}$ to 5 feet from the surface. From this, and from the information I obtained from others, I am safe in saying that the frost penetrates here on an average 5 feet, except when we have had a great depth of snow in the beginning of winter, in which case it does not penetrate nearly so far. The bluffs referred to are groves of poplar from 3 to 6 inches in diameter, on the edge of an open plain."

Prof. Charles Carpmael, Director of the Meteorological Service of Canada, to whom most of the above reports were addressed, remarks:—"We can easily imagine that at a depth of 17 feet at Prince Albert, there might be no frost at all in winter, but owing to the slow travelling downward of the wave of cold, it might have reached a depth of 17 feet in the early summer.

"It is easily seen that the annual mean temperature of the air might be considerably below the freezing-point without the occurrence of permanently frozen soil, for in winter the soil is often covered deep in snow, so that the temperature of the soil might be but little below 32°, although the temperature of the air were 30° or 40° F. below zero. Again, the heat which had entered the soil in summer would only be removed by slow conduction, whereas the summer heat would not only travel downwards by conduction, but be carried into the soil by percolation of the warm water through the surface."

19. Lat. 50° 30′, long. 103° 30′, the Bell farm, near Indian Head.—Frozen soil is said to have been met with in the summer of 1884 at a depth of $12\frac{1}{2}$ feet; details are wanting.

20. Lat. 49° 53′, long. 97° 15′, city of Winnipeg and the neighbourhood.—Mr. Ch. N. Bell reports that frozen soil has been found as under in various cemeteries.

Brookside Cemetery on the open prairie close to the city, soil rich black loam, varying in depth from 1 to 2 feet, subsoil heavy grey clay.

		On the Higher Ground Ft.	In.	On the Lower Ground Ft.	In.
December 23, 1884	... Frozen to	0	10	2	2
January 3, 1885	... ...	1	0	3	0
March 21, ,,	... ...	1	4	3	6
May 6, ,,	... ...	4	4	5	0
June 25, ,,	... None down to	6	0	6	0
January 14, 1886 ...	...	0	10	1	6

A further communication of June 1, 1886, states that the frost only descended 3 feet 6 inches on the higher ground in the winter of 1885-86, and had at that date disappeared. It descended 5 feet in the lower ground, but had almost disappeared.

At. St. John's Cemetery in the city, "I am advised by the clergyman," says Mr. Bell, "that frost has been found at from 5 to 8 feet depth"; careful investigation will be made there this year.

St. Boniface, a suburb of Winnipeg to the east.—The frost penetrates from 5 to 8 feet, according to the season, varying locally under the conditions of the exposure, tillage, dryness, and heat or frost cracks. During the summer of 1885 frost was found at a depth of 5 feet, and down to 7 feet, when the work was stopped. This was in July or early in August. The locality was probably exposed to the action of the sun.

21. Lat. 49° to $49\frac{1}{2}$°, long., in the valley of the River Pembina to the extreme south of the North-West Territory.—Dr. Alfred Selwyn, Director of the Geological Survey of Canada, who has two sons settled in this region, states that those gentlemen have had several wells sunk, the deepest about 40 feet, and have never seen any permanently frozen ground. There is similar negative evidence from Brandon, a little further north.

It would be premature to draw any general conclusions from the observations thus far collected. There is want of proof of the existence of permanent ground ice beyond the district of Mackenzie River in the North-West, but frozen soil has been shown to exist at a depth of 17 feet at Fort Simpson, at Prince Albert, and at Yorkton, and it may be questioned whether the wave of summer heat has time to descend to such a depth before it is overtaken by the refrigerating influence of the early winter. It certainly exists also in the neighbourhood of Hudson's Bay, on the eastern side, and it is evident that under favourable conditions frost, without being permanent, may in some cases last in the soil all the year round over a wide area, and in other years disappear.

At whatever level we locate the maximum of absorbed heat, it must be remembered that when the winter sets in, and freezes the surface, which it does rapidly to the depth of a foot or two, the heat will then be abstracted in both directions, and its rate of descent checked.

Report of the Committee, consisting of Sir Joseph D. Hooker, Sir George Nares, Mr. John Murray, General J. T. Walker, Admiral Sir Leopold McClintock, Dr. W. B. Carpenter, Mr. Clements Markham, and Admiral Sir Erasmus Ommanney (Secretary), appointed for the Purpose of Drawing Attention to the Desirability of Further Research in the Antarctic Regions.—Your Committee, after having given full consideration to the great importance of effecting a further exploration of the Antarctic Polar Sea, desire, in the first place, to express their opinion that it would be most essential, before approaching Her Majesty's Government with the view of urging the expediency of equipping such a naval expedition as would be required for the carrying out an exploration of such magnitude, interest, and importance, that the requirements for its success and a plan of operations should be most carefully considered, and the results embodied in a written form for the approval of the Council of the Association and for the information of the Government. Furthermore, in order to obtain the co-operation which the matter requires from eminent men in science, your Committee feel it necessary for their body being enlarged by the addition of influential members of the Association, and of other bodies representing the various branches of science interested in the investigation of this comparatively unknown region, and especially of the Royal Geographical Society. Your Committee have to point out that our knowledge of the South Polar region is chiefly confined to the grand discoveries effected by that celebrated expedition under the command of Capt. Sir James C. Ross, conducted between the years 1839 and 1843 with sailing-ships. Since that period the facilities for effecting a more complete research have been greatly augmented by the application of steam propulsion to vessels better adapted for ice-navigation.

This has been proved by continuous experience in the Arctic seas during the late half-century. For the above reasons your Committee deem it desirable to defer making their report, with a view to giving more definition to the objects sought to be obtained and to the best means of obtaining them, as also to expand this Committee, in order to elicit to the fullest extent the opinions and to secure support from those conversant with the various branches of science which are to be investigated during an exploration which, from its very important and serious nature, eminently merits the favourable consideration of this great and enterprising maritime nation.

NOTES

THE 59th annual meeting of the Association of German Naturalists and Physicians will take place at Berlin from the 18th to the 24th inst. General meetings will be held on the 18th, 22nd, and 24th, the sections, of which there are thirty, meeting at other times when and where they wish in the various places offered them for that purpose. At the same time there will be an exhibition of scientific apparatus, instruments, and educational objects. On the morning of each day a journal will be issued containing information of interest to members, and as much as possible of the proceedings at the various meetings of the preceding day. The Physical Section is under the Presidency of Dr. von Helmholtz and Dr. Kirchhoff. Amongst the papers to be read are the following:—The microscope as an aid to physical investigation, by Dr. Lehmann; the determination of the electro-chemical equivalents of silver, by Dr. Köpsel; electrical discharges, by Dr. Goldstein; on Palmieri's investigations into the development of electricity in the condensation of steam, by Dr. Kalischer. The Presidents of the Chemical Section are Drs. Hoffmann and Landolt. In this Section there will be papers on silver oxydul, by Herr von der Pforten; a new synthesis of naphthaline derivatives, by Dr. Erdmann; and on a peculiar phenomenon of reaction, by Herr Liebreich. In the Botanical Section there will be papers on Goethe's influence on botany, and on the reception of water by the external organs of plants. In the Zoological Section papers will be read on dual eyes in insects, on the origin of the frontal ganglion in Hydrophilus, on freshwater Bryozoa, the Protozoa of Kiel Bay, on the boundaries of zoo-geographical regions from the point of view of ornithology, the fauna of North German lakes, and on the old Peruvian domestic dog. In the Section for Geography and Ethnology there will be several papers on Africa, especially on the Congo region; one on the Kurds, others on South Polar exploration, on the Goajira Indians, and on the importance of the Xingu for the ethnology of the northern part of South America. A great majority of the sections are occupied with medical subjects. One of these will be devoted to the discussion of the condition of Europeans in different climates, their diseases, acclimatisation, &c. The last section of all is devoted to scientific education.

SIR HENRY ROSCOE has given notice that in the next session of Parliament he will call attention to the Report of the Departmental Committee on the National Science Collections, and will move a resolution.

IN reply to a question by Sir John Lubbock in the House of Commons on the 9th inst., the Chancellor of the Exchequer stated that the appointment of a Minister of Education, as recommended by the Committee of 1884, had not yet come under the notice of the Government, nor could he hold out any hope that it would be likely to come very soon under its notice. Lord Randolph Churchill said he suspected the proposal would involve an increased charge upon the public revenues, "and every alteration, reform, or modification of a department which would involve an increased charge possesses in my eyes an incurable defect."

EARTHQUAKES have continued at Charleston during the past week, but the shocks are decreasing greatly in frequency and violence. One occurred on Saturday night and one on Sunday, but no harm was done by either. The Mexican Government has been officially informed that Tequisixtlan was shaken by an earthquake at 4.30 on the morning of September 3. The movement was from east to west. A Naples correspondent of the *Times* writes that the shock of the 28th ult. was severer than any which has been felt for some years. The panic was therefore great, and was increased by superstition. There were two shocks—one was horizontal, the other vertical, but they followed each other in such rapid succession that they appeared to be one shock, and for many hours after the replica was expected with much apprehension. The shocks occurred about 11 p.m., and were felt severely at every place in the Bay of Naples, and in the Island of Capri, which has no volcanic element in its formation. Similar reports were received from Puglia, Calabria, and Sicily, where the shock was very severe. At Forio, in the Island of Ischia, it was felt, and created a panic. Vesuvius has long been in a state of comparative repose Prof. Palmieri says that at 4 p.m. on the 28th it showed signs of renewed activity by frequent thunders, and by throwing masses of lava into the air.

MR. POND, the Government Analyst of New Zealand, has proved by actual experiment that the dust thrown out during the recent volcanic eruptions is of a highly fertilising kind. He obtained samples of the dust from three different places, and sowed a quantity of clover and grass seeds in each. The soil was kept moistened with distilled water, so that no manurial elements might be imparted by the water used. In all cases the growth was almost as vigorous as in rich volcanic soil. The rapid growth of the plants and their colour show that the dust is a benefit to the soil on which it has fallen.

THE programme for the autumn meeting of the Iron and Steel Institute, which is to be held in London on October 6, 7, and 8 next, has just been issued. The Council of the Institute has arranged to hold the meeting in London this year, for the second time in the history of the Society, with a view to affording Members the opportunity of studying the mineral resources, &c., of the colonies, as illustrated by what is shown at the Exhibition, and of coming into contact with colonists and Indians who are interested in mineralogical operations. That being so, perhaps the most interesting paper in the list is one on the iron-making resources of our colonies, prepared by Mr. Gilchrist (whose name is associated with the well-known basic process) and Mr. Edward Riley. Among other papers to be read there is one on the chemical composition and mechanical properties of chrome steel, by M. Brustlein; another on combustion with special reference to its application in the arts, by Mr. F. Siemens; another on the treatment of high-class tool steel, by Mr. A. Jacobs, of Sheffield; and one on modifications of Bessemer converters for several charges, by Mr. John Hardisty, of Derby.

THE Paris Academy of Sciences has issued in separate form the text of the discourses pronounced at the Museum of Natural History on the occasion of M. Chevreul's centenary, August 31, 1886. The speakers were M. Fremy, Director of the Museum; M. Jules Zeller, President of the Institute; M. Janssen, on behalf of the Academy of Sciences; M Broch, Corresponding Member of the Institute; Colonel Le Mat, in the name of the Washington National Institute; M. Ressmann, Italian Plenipotentiary; M. Gilbert Govi, President of the Neapolitan Academy of Sciences; M. de Bouteiller, on behalf of the Paris Municipal Council and the General Council of the Seine; M. Chaumeton, President of the Association of French students; MM. Nadault de Buffon, Dehérain, Leroy, Auguste Vitu, Gerspach, and René Goblet. The brochure is printed in uniform size and type, with the weekly *Comptes rendus* of the Academy.

THE Paris newspapers have published a congratulatory communication from the Academy of Sciences in Berlin to M. Chevreul, from which the following is an extract:—"He who would form a complete idea of your so busily occupied life should follow the entire course of your creative activity, which has been directed to all departments of chemistry. He must follow all the innumerable detailed researches which have enabled you to determine the nature of various minerals and of a large number of salts, as well as the composition of many organic matters. He should study your chemico-physiological works, by which you have made such great advances towards the knowledge of the most important secrets of the animal organism as well as your labours on the most varied questions of public hygiene. He ought to follow the excursions which enabled you to fix the laws of the contrasts among colours, and to class them systematically and scientifically. He ought to study your lectures on the chemical principles of dyeing. He should finally imagine himself at the period when misty ideas of the most false and fantastic kind threatened to surround and obscure the mind, and when, with the record of history in your hands, you dissipated the mists by making your countrymen recognise in the delusions of the past the errors of the present time. Having thus represented in all its extent the activity that you have shown throughout your long life, we hold that your name should be inscribed in one of the first places on the list of the great men who have carried the scientific glory of France to the extremities of the earth."

IN a long communication to the *Times* of September 7 from its Correspondent with the Grenada Eclipse Expedition, it is stated that a botanical garden is in course of formation under Mr. Elliott, with a view to the development of the resources of the island. Mr. Elliott, the article goes on to state, "has made frequent excursions into the high woods for the latter purpose, and the results of his botanical exploration of the island, which will soon be made known, are very satisfactory, many valuable woods having been found. It is hoped by means of the botanic garden to encourage the planters of the Windward Islands to cultivate the minor products of this fertile region, and especially to improve their fruits by exhibiting the finest kinds in the gardens brought from other regions and giving information showing how it can be done. No more healthy sign of the progress of the colony could be afforded than in the enterprise of the Colonial Government in establishing such a garden and the interest taken in it by the planters of the island. So much for applied botany. During the stay of the Expedition pure botany has been studied with much success by Mr. George Murray, of the British Museum, the naturalist attached to the Expedition, who arrived a fortnight before the observers of the eclipse to gain the necessary time for finding good working grounds. His special mission is an inquiry into the life-history of certain marine *Algæ* called the *Siphoneæ*. The forms of this group are well enough known to European botanists, but the development and life-phenomena of most of the genera composing it have not yet been investigated. He has been greatly gratified to find an abundant supply of material for his special research, though the island is poor in *Algæ* owing to the small rise and fall of the tide, which exceeds a foot only at spring tides. The operation of examining this material is conducted in a well lighted and very convenient room set apart for the purpose by His Excellency the Governor, who has in this instance, too, shown the greatest sympathy with the object of the work, and an unfailing helpfulness towards its accomplishment. So far as the examination of the material collected has gone, it promises to yield an answer to the question of the nature of the reproduction and development of the types investigated, but whether the information will result in fixing definitely the position of the *Siphoneæ* as a group or in the breaking up of the group and the incorporation of certain genera into other orders, already better known, cannot, of course, yet be determined. The land and marine fauna are also engaging Mr. Murray's attention to the extent of collecting these, and the reptiles and small mammals have in this department of work been kept particularly in view."

MR. JOHN TAYLOR, a pupil of Dr. Marshall Ward, who went out some time ago as botanist to the Bahamas Government, is evidently pursuing his work under difficulties. While he and his companions were on shore at Acklin Island, 30 miles from Long Cay, on August 13, the cook, a Haytian, who was left in sole charge of the vessel, made off with it under cover of darkness, and up to the 19th no trace of ship or cook was found. Mr. Gardiner had on board nearly all his scientific books, and all the instruments, &c., necessary for a month's good work. He lost everything of that kind he had, including his Zeiss microscope; besides all his manuscript scientific diary, and list of the Bahamas flora, not to mention a sum of money, bedding, &c. His total loss he estimates at 75*l.*; we are sure the Bahamas Government will not allow Mr. Gardiner to sustain a loss which to him must be serious.

THE translation of an English botanical book into German is so much a reversal of the present fashion that it is of some interest to know that a translation of Dr. Maxwell Masters' "Vegetable Teratology" has been made by Mr. Udo Dammer, and published by Haessel of Leipzig. Many additional notes have been added by various German and Italian botanists, as well as by Dr. Masters, and some additional woodcuts provided.

THE celebrated waterfall of Teverone, which Horace calls "*præceps Anio,*" has been employed to put in operation two dynamos of 100 horse-power for the illumination of the city of Tivoli. Others are being fitted up. The motive power, which is to be utilised by a company from the designs of M. Cantoni, is equivalent to several thousand horses. The illumination of Rome is contemplated, as well as the distribution of force to a distance from the station. The excavations and canals are conducted under the house of Mæcenas, which is described as situated at *udum Tibur*, now Tivoli.

TWO more of the Paris theatres are now illuminated by incandescent light—the Palais Royal by Edison, and the Variétés by Woodhouse. With the Opera and the Eden Theatre this brings the number up to four. Every evening the Industrial Exhibition at the Palais des Champs Elysées is lighted also by electricity.

WE have received a copy of a paper read by Mr. H. C. Russell before the Royal Society of New South Wales, on "Local Variations and Vibrations of the Earth's Surface," in which he records his own experiences on this subject in the hope that other astronomers will do the same, and thus by united action assist in the work of tracing these vibrations and changes. Mr. Russell's observations took place at Lake George, and were made chiefly by means of an automatic recorder of the height of the water in the lake. Although the instrument used has not the extreme sensitiveness to minute vibrations which Mr. Darwin's reflecting mirror and similar instruments have, yet it was so placed that all such changes became magnified by the relatively enormous extent over which it extends its sensitive part, if this expression may be used; for any change in gravity, or the direction of the vertical, is not seen as it affects the base of a small instrument a few feet square, but as it affects a surface 20 miles long and 5 to 6 miles wide. Barometric and wind changes, too, so difficult to see in other instruments, at once became evident here by their effects on such a large body of water, and the lake-gauge for these reasons is not only capable of showing changes quite as minute as the Cambridge pendulum apparatus, but also of keeping a perfectly satisfactory record of

these changes, so written that many, if not all, the causes can be traced in the curves which they produce. Various tables and diagrams are appended to the paper.

COLONEL GILDER has started from Winnipeg on his expedition to the Arctic regions, with the object of reaching the North Pole.

THE deaths are announced of M. Paul Soleillet, the explorer of Shoa in North-East Africa, and of Herr Robert Flegel, the explorer of the Niger and Binué.

THE celebrated traveller and botanist, Dr. Schweinfurth, lectured recently at Berlin on the Kew Botanical Gardens, which he characterised as the finest in the world. Kew, he said, is the Botanical Foreign Office for all nations, for it is the centre of all botanical news from all parts of the world.

WE have received "An Account of the Progress of Astronomy in the Year 1885," compiled for the Smithsonian Institution by Prof. W. C. Winlock. The investigations reviewed comprise (among others) Prof. Pritchard's photometric researches as consigned in the Oxford "Uranometria," M. Dunér's catalogue of stellar spectra of the third type, Drs. Gill and Elkin's determination of southern star-parallaxes, Prof. Bakhuysen's of the rotation-period of Mars, Prof. de Ball's of the nutation constant, Prof. Peters' of the orbit of 61 Cygni, and Prof. Langley's inquiries into the temperature of the moon's surface. M. Faye's theory of the origin of the solar system, with Prof. G. H. Darwin's criticisms upon it in NATURE, are prominently dealt with. We hear with pleasure of the progress towards completion of Prof. Rowland's photographic map of the normal solar spectrum. The amount of detail contained in it may be judged of from the one fact that 120 lines are visible between H and K, the original negatives showing 150. The most striking astronomical events of the year, *i.e.* the outburst of new stars in Andromeda and Orion, the photographic discovery of a nebula in the Pleiades, and the meteoric shower of November 27, are chronicled in due and interesting detail. Seven comets were observed in 1885, of which five were seen for the first time, the others being expected returns of Encke's and Tuttle's. Nine minor planets were discovered. The Report concludes with a useful bibliography of astronomical works published in 1885.

IN March, 1884, Prof. Holden offered to observe at the Washburn Observatory the 303 fundamental stars for the southern zones of the "Astronomische Gesellschaft." The offer was accepted; the work was begun May 2, 1884, and finished December 25, 1885. The results are contained in vol. iv. of the "Publications of the Washburn Observatory," now before us. When Prof. Holden was appointed to the Lick Observatory in October 1885, 468 observations were still wanting to complete the series. These were very creditably supplied, before the end of the year, by his assistants, Mr. Updegraff and Miss Lamb. In all, 6444 observations were made with the Repsold meridian-circle; each star of the 303 was completely observed six times; and instrumental constants were determined for each night. No pains were spared to secure accuracy. The probable error of a single bisection of Polaris was estimated at not above $0''.1$ for poor seeing, and $0''.05$ under the most favourable conditions. A list of corrections to standard star-catalogues (p. 69) forms a valuable addition to the contents of the volume.

WE have to acknowledge the receipt of the Calendars for the Session 1886-87 of the University Colleges of Dundee and Bristol, and of the Durham College of Science of Newcastle-on-Tyne.

THOSE interested in natural history will be glad to hear that Mr. Quaritch issues this week vol. iii. (the "Quadrupeds") of the Memorial Edition of "Bewick's Works," which he is publishing—to be complete in five volumes.

THE additions to the Zoological Society's Gardens during the past week include a Spring-bok (*Gazella euchore* ♂) from South Africa, presented by Capt. John Hewat, C.M.Z.S.; two Talapoin Monkeys (*Cercopithecus talapoin*) from West Africa, presented by Mr. R. E. Dennett; two Red-headed Finches (*Amadina erythrocephala* ♂ ♀) from South Africa, two Saffron Finches (*Sycalis flaveola* ♂ ♀) from Brazil, presented by Mr. H. B. James; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mr. J. Davis; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Herring Gull (*Larus argentatus*), British, presented by Mr. E. Penton, jun., F.Z.S.; a West African Python (*Python sebæ*) from West Africa, presented by Major A. Morton Festing; a Smooth Snake (*Coronella lævis*) from Hampshire, presented by Mr. W. H. B. Pain; a Leonine Monkey (*Macacus leoninus* ♂) from Arracan, deposited; two Crested Pigeons (*Ocyphaps lophotes*), a Geoffroy's Dove (*Peristera geoffroii*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE INNER SATELLITES OF SATURN.—Writing in the *Astronomische Nachrichten*, No. 2743, Prof. Asaph Hall states that he has now finished the reduction and discussion of the observations of Titan and the five inner satellites of Saturn made at Washington since the mounting of the 26-inch refractor in 1873. These observations have been made with the filar micrometer, and most of them are observed angles of position and distances. The average probable error of a single observation for the position of a satellite is $\pm 0''.27$. A remarkable result of the discussion is that the Washington observations of the five inner satellites can be satisfied within the limits of their probable errors by circular orbits. At the beginning of this discussion Prof. Hall hoped that the observations would determine the positions of the lines of apsides with such accuracy that the motions of these lines would be known, and that thus we might obtain data for a new determination of the mass of the Ring, and of the figure of the planet. But the resulting circular orbits for the inner satellites make the position of a line of apsides indeterminate, and for the present the mass of the Ring remains unknown.

On account of the difficulty of making good micrometrical measurements of the inner satellites of Saturn, astronomers have revived the old method of observing their conjunctions with the ends of the Ring, or with some other marked feature in the Saturnian system. A series of observations of conjunctions with the ends of the Ring was made at Toulouse in 1876 and 1877 by MM. Tisserand and Perrotin; and in order to test the old method of observing, Prof. Hall has compared these measures with his elements of the five inner satellites. The result at which he arrives is that the probable errors of a single residual are larger for the Toulouse observations ($= \pm 0''.41$ in the mean) than in the micrometrical measurements at Washington. Prof. Hall therefore concludes that observations of these satellites with filar micrometers are among the best we have, and since they are definite measurements, and are made in very different positions, a result deduced from them is more likely to be free from constant errors. He suggests that probably the best way to effect an improvement in such measurements is to devise some new arrangement of the wires of the filar micrometer.

THE INVENTION OF THE SEXTANT.—Dr. J. L. E. Dreyer points out, in the *Astronomische Nachrichten*, No. 2739, an historical error which has crept into several astronomical works, although it was refuted some fifty years ago by Prof. Rigaud in a series of papers communicated to the *Nautical Magazine*. In the books referred to, it is stated that the principle of the construction of the sextant was communicated to John Hadley by his brother, a Capt. Hadley, who had in his possession a sextant given to him by Capt. Godfrey, brother of Thomas Godfrey, of Philadelphia, the real inventor of the instrument. But it appears there never was such a Capt. Hadley. The brothers of John Hadley were—one a barrister, the other a physician; and he himself was not an instrument-maker by profession (as has been asserted), but, as an amateur, occupied himself with mechanical pursuits, and was the first to bring the polishing of reflecting-telescopes to any perfection. On May 13, 1731, John Hadley

communicated to the Royal Society a description of his reflecting octant; and, after some hesitation, Halley declared himself satisfied that Hadley's idea was quite different from that of Newton, who had invented an instrument founded on the same principle. It is no doubt true that Thomas Godfrey, a glazier of Philadelphia, had invented an instrument of this kind about the year 1730; but the first intelligence of his invention did not reach England before the month of May 1732, in a letter from James Logan to Halley. Godfrey's instrument was made of wood by Edmund Woolley, a carpenter, about November 1730, and had been tried on board the ship *Truman*, of which John Cox was master. The first model of Hadley's octant had, however, been constructed by his brother George about the middle of the summer of 1730. The thanks of those interested in the history of astronomy are due to Dr. Dreyer for the effort which he has made to correct the errors on this point which are found in Poggendorff's "Biographisch literarisches Handwörterbuch," in Wolf's "Geschichte der Astronomie," and elsewhere.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *SEPTEMBER* 19–25

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 19

Sun rises, 5h. 43m.; souths, 11h. 53m. 42·7s.; sets, 18h. 5m.; decl. on meridian, 1° 25′ N.: Sidereal Time at Sunset, 17h. 59m.

Moon (at Last Quarter September 21) rises, 20h. 39m.*; souths, 4h. 7m.; sets, 11h. 44m.; decl. on meridian, 15° 12′ N.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury ...	4 55	11 29	18 3	6 0 N.
Venus ...	3 50	10 45	17 40	9 56 N.
Mars ...	10 44	15 11	19 38	18 12 S.
Jupiter ...	7 7	12 52	18 37	3 43 S.
Saturn ...	23 34*	7 37	15 40	21 32 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

Sept.	Star	Mag.	Disap.	Reap.	Corresponding angles from vertex to right for inverted image
			h. m.	h. m.	° °
20	130 Tauri	6	23 34	0 30†	68 229
21	26 Geminorum	5½	22 46	23 26	23 273
25	B.A.C. 3345	6	1 53	2 41	61 206

† Occurs on the following morning.

Sept.	h.	
22	12	Saturn in conjunction with and 3° 29′ north of the Moon.
23	—	Sun in equator.

M signifies maximum; *m* minimum.

Meteor Showers

The following are amongst the showers of the period:—Near θ Cassiopeiæ, R.A. 14°, Decl. 50° N.; near α Arietis, R.A. 31°, Decl. 18°; and near Polaris, R.A. 68°, Decl. 87° N.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

University College, London.—We notice from the prospectus of the Engineering Department that the examination for the Gilchrist (Entrance) Engineering Scholarship of 35*l.* per annum is to be held on the 28th and 29th inst. Candidates must be under nineteen, and the subjects of examination are:—(1) Mathematics; (2) any two or more of the following—(*a*) mechanics, (*b*) mechanical drawing, (*c*) examination on some subject connected with engineering, (*d*) French or German, (*e*) the use of tools. The examination is intended to be of such a standard as can be passed by lads from school who have begun to acquire some knowledge of mechanical pursuits. The appliances of the engineering laboratory (under Prof. Alexander B. W. Kennedy) have been very much extended during the past year, mainly through a grant from the Gilchrist Trustees, and are now very complete in the direction both of experiments in elasticity and the strength of materials, and in the economic work of engines and boilers. Laboratory work is so arranged that students go through a systematic course of experimental instruction in these and other connected subjects during the session.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 6.—M. Émile Blanchard in the chair.—On presenting to the Academy a copy of a volume issued on the occasion of M. Chevreul's centenary, August 31, 1886, M. Berthelot remarked that this seemed a suitable occasion for reviving the old custom of celebrating Academic solemnities by the publication of special scientific and literary essays. The present work, in the preparation of which MM. Ch. Richet, G. Pouchet, E. Grimaux, E. Gautier, Dujardin-Beaumetz, E. Demarçay, and Berthelot had co-operated, has been executed with rare taste and care by the editor, M. Alcan, and by him dedicated to M. Chevreul on behalf of himself and his fellow-contributors.—Fluorescence of the compounds of manganese subjected to electric effluvium in vacuum, by M. Lecoq de Boisbaudran. In the experiments here described the author has aimed especially at determining the effects due to the presence of manganese. The fluorescence of some of its compounds is an extremely sensitive reaction, by means of which imponderable traces of this metal may be detected in natural or artificial substances that might otherwise be supposed free from its presence.—Paralytic ataxy of the heart, by M. Mariano Semmola. In this communication the author resumes the results of his further observations on cardiac disorders, already reported in the *Transactions* of the International Medical Congress, seventh session, London, August 1881.—Remarks in connection with three Italian essays submitted to the Academy, by M. Govi. The first of these papers deals with an episode in the life of Galileo, showing that the hostility of the Jesuits to the Florentine philosopher was not due to the letter addressed by him to his brother in 1606, announcing the expulsion of the Order from Venice. The second describes a curious plano-convex lens executed by Torricelli some time between 1644 and 1647, and recently discovered in the Cabinet of Physics attached to the University of Naples. The third refers to an unpublished letter written by Volta in 1785 on Lavoisier's pneumatic theory, which, although not accepted without reservations, is defended against the assumptions of an Englishman named Lubbock, who had essayed to transform oxygen into a new principle called by him the "sorbile principle."—On certain differential equations of the first order, by M. Roger Liouville. It is shown that the differential equation—

$$y' + a_1 y^3 + 3a_2 y^2 + 3a_3 y + a_4 = 0,$$

is reducible to the quadratures if its coefficients $a_1, \ldots a_4$ and their derivatives $a'_1, \ldots$ satisfy the equation—

$$a_1 L' + KL^{\frac{5}{3}} - 3[a'_1 + 3(a_2^2 - a_1 a_3)] L = 0,$$

where L represents the combination

$$L = a_2 a'_1 - a_1 a'_2 + a_1 (a_1 a_4 - a_2 a_3) + 2a_2 (a_2^2 - a_1 a_3,$$

and K an arbitrary constant which may vanish.—Note on the

theory of dissociation, by M. G. Chaperon. It is argued that the theory of dissociation may be expressed with simplicity by means of certain cycles, which are easily formed, if the possibility be admitted of separating at a constant temperature several mixed gases or vapours without the expenditure of convertible labour or of heat.—On the conjugation of the Paramecia, by M. E. Maupas. Fresh observations on *Paramecium caudatum* have led the author to the determination of a fact of great physiological importance, which had hitherto escaped his notice, and which seems to foreshadow in these organisms the fecundating processes of the higher animals.—On the family of the Polyclinians, by M. Lahille. The Polyclinians of Roscoff—studied, for the first time, in 1872 and 1873, by M. Giard—are here divided into two distinct families—Polyclinidæ and Aplididæ.—On the affinities of the Eocene ferns of West France and Saxony, by M. Louis Crié. The already-determined affinities of the Tertiary flora of these two regions are here considerably enlarged by a comparative study of their respective ferns.—Note on the telluric currents, by M. J. J. Landerer. The author's further observations on meteorological phenomena connected with electricity lead to the general inference that the great telluric current of the globe has its origin in the difference of the negative potentials. The constancy and amplitude of the *régimes* of the winds whence it results insure both its normal direction and permanence.—On the discovery made in Belgium of a grave contemporary with the mammoth and rhinoceros, by M. Nadaillac. In a cave recently explored by MM. Marcel de Puydt and Sohest near Spy, in the province of Namur, were discovered two skulls of the Neanderthal type associated with the remains of *Rhinoceros tichorhinus* and *Elephas antiquus* (?). It thus appears that the Neanderthal race had already penetrated to the Meuse valley in the remotest times. From the relics found in the undisturbed soil of this cave it appears that they could make flint implements, utilise the tusks of the mammoth, manufacture earthenware baked in the fire, that they buried their dead, and in a word possessed the first rudiments of civilisation.

BERLIN

Chemical Society, July 12.—C. Scheibler, Vice-President, in the chair.—Ferd. Tiemann gave an account of some reactions of substituted amidoximes.—C. Scheibler discussed the important question for the sugar industry, whether a definitely characterised strontium dihydrate ($SrO,2H_2O$) exists as such, or whether the substance having the percentage composition of a dihydrate is not rather a monohydrate (SrO,H_2O) containing a higher hydrate mixed with it. He described his experiments on the action of carbon dioxide on the hydrates of the alkaline earths at different temperatures and containing varying amounts of water. He finds that the facts agree with the latter view.—H. Noerdlinger has studied the oxidation products obtained by the action of nitric acid on myristic acid: the chief products are succinic and adipic acids, besides smaller quantities of glutaric, pimelic, suberic, oxalic, and carbonic acids.—R. J. Friswell and A. G. Green described their researches on the constitution of diazoamidobenzene, from which it is concluded that the constitutional formula $C_6H_5 . N : N . NH . C_6H_5$ usually assigned to it is the correct one.—M. Rosenfeld described lecture experiments for the demonstration of the volumetric decomposition of hydrochloric acid and of the sublimation of sulphur.—J. Bongartz gave an account of compounds which aldehydes, ketones, and ketonic acids give with thioglycolic and thioacetic acids.—R. Otto discussed the conditions under which the whole of the arsenic can be removed from hydrochloric acid by hydrogen sulphide, and he showed that the last traces of arsenic can be precipitated when the addition is made of a certain quantity of a substance which gives an insoluble precipitate with the hydrogen sulphide. Since crude hydrochloric acid always contains such substances (*e.g.* ferric chloride, chlorine, &c.), it can readily be freed from arsenic by means of hydrogen sulphide.—P. Klason gave an account of a new method for the estimation of sulphur and of the halogens in organic compounds by burning them in a current of oxygen.—H. Kiliani has isolated the lactone of levulosecarboxylic acid, and has more closely examined the pentoxypimelic acid resulting from the oxidation of dextrosecarboxylic acid, and also its lactone.—E. Fischer has obtained a base named isoglucosamine, $C_6H_{13}NO_5$, by the reduction of phenylglucosazone with zinc dust and acetic acid, aniline and ammonia being simultaneously produced; isoglucosamine is isomeric with glucosamine, and closely resembles the latter in its properties, and probably bears the same relation to levulose as glucosamine does to dextrose.—J. Tafel described a new method of preparing primary amines, which consists in the action of sodium amalgam and glacial acetic acid on the alcoholic solution of the substances produced from ketones or aldehydes and phenylhydrazine; the reaction takes place according to the equation—

$$R : N_2H . C_6H_5 + 4H = RH . NH_2 + NH_2 . C_6H_5.$$

—E. Erlenmeyer offered an explanation of the remarkable isomerism occurring in the cinnamic acid and acrylic acid series.—K. Heumann and Th. Heidlberg are experimenting with a view to ascertain the influence exerted on the shade of certain dyes by the introduction of substitution groups and elements: in the present communication they describe the effect produced by the introduction of chlorine.—W. Staedel and H. Bauer gave an account of their experiments on the methylation of metanitraniline; on the demethylation of tertiary aromatic amines, and also on a convenient method of preparing azo-compounds.—G. Ciamician and P. Silber had a paper on the constitution of certain di-substitution derivatives of pyrroline.—K. Elbs and G. Steinike have studied α-naphthylphenylketone.—W. Kelbe has found ordinary cymene and an aromatic hydrocarbon of the formula C_9H_{12} in rosin-spirit.—R. Anschütz and P. N. Evans have found that antimony pentachloride boils under diminished pressure without appreciable decomposition.—A. G. Ekstrand gave the results of his research on the naphthoic acids; he has prepared and described the various nitro-derivatives.

BOOKS AND PAMPHLETS RECEIVED

"American Journal of Mathematics," vol. viii. No. 3.—"18th and 19th Annual Reports of the Trustees of the Peabody Museum," vol. iii. Nos. 5 and 6 (Cambridge, Mass.).—"Field and Other Experiments Conducted on the Farm and in the Laboratory of Sir J. B. Lawes, June 1886."—"A History of the Theory of Electricity," vol. i., by Isaac Todhunter and Karl Pearson (University Press, Cambridge).—"Industrial and High Art Education in the United States," by J. E. Clarke (Washington).

EXTERIOR BALLISTICS

Exterior Ballistics in the Plane of Fire. By James M. Ingalls, Captain First Artillery, U.S. Army, Instructor. (New York: D. Van Nostrand, 1886.)

CAPTAIN INGALLS has succeeded in presenting within the limits of 128 pages, for the most part a very good and complete account of the various methods now in use for calculating range tables and solving important problems relating to trajectories of shot. The subject of ballistics is divided into three parts—interior ballistics, which treats of the motion of the shot within the bore of the gun, of which very little is known; exterior ballistics, which deals with the motion of the shot after leaving the muzzle and till it strikes an object; and the remaining part treats of the penetration into an object struck. The author confines his attention to exterior ballistics. His book is purely mathematical, but well adapted to the wants of the artillerist. It is in reality a second edition.

In Chapter I. theoretical resistances are calculated for various forms of heads of elongated shot; and Chapter II. is devoted to the consideration of experimental resistances, where reference is made to the experiments of Robins (1742); Hutton; Piobert, Morin, and Didion (1839-40); Virlet (1856-58). Then follows a brief notice of experiments made with the Bashforth chronograph at Shoeburyness. The dates of the publication of the first and final reports of these experiments are correctly given 1870 and 1880 respectively, but there is no notice of an intermediate report (84/B/1879), printed by Government and circulated in 1879, giving coefficients of the resistance of the air for elongated shot for all velocities between 430 and 2250 f.s. (131 and 686 m.s.). But the first publication of the results of these experiments will be found in the *Transactions* of the Royal Society for 1868 for velocities 900 to 1600 f.s. (p. 441). Mention is then made of some rather meagre experiments said to have been made by Mayevski in 1868-69 with both spherical and elongated shot. In the latter case the assistance derived from the results of the English experiments is fully and candidly acknowledged by Mayevski, whose results it appears were not published till 1872. And lastly, Mayevski's and Hojel's discussion of Krupp's experiments made at Meppen (1881) are noticed. Some confusion is caused here from the intermixture of dates of experiments and dates of their publication, but it must be evident that the publication of Bashforth's results was not anticipated by any experimenter here named for the whole range of velocities 100 to 2800 f.s. for elongated shot, and for velocities 850 to 2150 f.s. for spherical shot, excepting in the latter case the results of Robins, Hutton, and Didion.

Capt. Ingalls then proceeds to explain the methods of determining the coefficients of resistance. He passes over the ballistic pendulum, which is however not yet quite obsolete, and first deals with the case where velocities of a shot are measured at two points a known distance apart. He gives a table of the 16 determinations of Didion's ρ' for spherical projectiles by Mayevski (published 1872), and then he passes on to Mayevski's and Hojel's formulæ for elongated shot (1882). It does not appear why priority is given to these recently published results. These being disposed of, the author gives a very good account of the manner in which Bashforth obtains his coefficients from the observed times occupied by the shot in passing over a succession of equal spaces (pp. 31-35). Capt. Ingalls has expressed the law of resistance from these English results in terms of the powers of the velocity, upon which he remarked that the expressions deduced by Mayevski and Hojel from the Krupp experiments give a less resistance. He does not consider at all the nature of the experiments from which these contradictory results were obtained, but at once comes to the desired conclusion that "This is undoubtedly due to the superior centring of the projectiles in the Krupp guns over the English, &c." But we very much doubt this statement. Further on, the experiments given in the 'Annexe à la Table de Krupp" are calculated by (1) Krupp's tables; (2) by Ingalls' tables (reduced by using $c = \cdot 907$, as had before been done in the *Proceedings* of the R. A. Institution, Woolwich, 1885); and (3) by Mayevski's formulæ. The agreement between calculation and experiment is apparently about equally satisfactory in all three cases. But the calculation by Ingalls' tables supposes a reduction of over 9 per cent. in Bashforth's coefficients used in calculating these tables. We have not had an opportunity of examining the Krupp experiments of 1881, from which Mayevski's formulæ of 1882 are said to have been derived, unless they be those contained in Krupp's Paper xxx., which gives the particulars of a few "expériences pour déterminer la résistance de l'air aux grandes vitesses." In that case we are informed that no less than *six* chronoscopes were used in *pairs* to measure velocities at 30, 130, and 1000 metres from the gun. This amounts to a confession that the particular instrument used was not to be relied upon. We have not space to pursue the question further, but we must direct particular attention to the group formed of rounds 7-10, fired July 5, 1881, stated as follows:—

Round		v at 30 m. No. 301	No. 302		v at 130 m. No. 292	No. 293		v at 1000 m. No. 114	No. 115
7	...	896·4	892·5	...	855·9	850·9	...	—	—
8	...	903·8	894·5	...	852·7	862·7	...	—	—
9	...	907·4	887·2	...	857·6	856·7	...	438·1	—
10	...	907·4	911·4	...	854·1	834·7	...	—	—
Means	...	903·8	896·4	...	855·1	851·3	...	438·1	—
		900·1 m.s.			853·2 m.s.			438·1 m.s.	

This is one of the six groups of rounds of which the experiment consists. It will be observed that there are large differences in some of the velocities measured at the same point by two different instruments, and that there is only a single velocity measured by one chronoscope at the distant station. It is quietly assumed that this one velocity of 438·1 m.s. determined from round 9 is perfectly correct and applies equally to all four rounds 7, 8, 9, and 10! All the results deduced from this group depend entirely upon this *single* velocity. Chronoscope No. 115 never came into action at all, and No. 114 only once. It is difficult to imagine a worse experiment. From all this it appears that it is necessary to be very cautious in

adopting the results of so-called experiments. It must be evident that the efforts of the Krupp party are directed to spread an impression that his system of constructing guns and projectiles has some mysterious property of reducing the resistance of the air. Now it is perhaps fortunate that the English experiments were made when the Service guns did not shoot quite so steadily as they do now, because all the observations were made near the gun when the motion of the shot was most nearly in the direction of motion. Although one gun was an extremely good one—we will suppose that the average of the four guns gave coefficients slightly above those due to perfectly steady motion in direction of the axis of the shot. Let us consider now what actually takes place on a long range. The elevation we will suppose 10°, and also that the shot leaves the muzzle with perfect steadiness. The tendency of the shot is to preserve the parallelism of its axis, but the curvature of the trajectory soon causes the axis of the shot to be inclined to the direction of motion. The resistance of the air then acts *obliquely* on the shot, and so tends to place the axis in the direction of motion. If it succeeded in accomplishing this feat at any instant, all would be out of order the next moment. In this way the axis is kept *nearly* in the direction of motion. Our shot would perhaps fall at an angle of 12°, making 22° as the angle through which the axis of the shot had been turned during its flight, by the *oblique action* of the resistance of the air. This oblique action of the air causes other disturbances, as "drift," &c. Thus if in the English experiments the shot moved with their axes at times slightly inclined to the direction of their motion they would give coefficients more nearly corresponding to the conditions of their motion on long ranges than if they had been obtained from shot moving with the axis exactly in the direction of their motion.

Afterwards Capt. Ingalls treats of the general properties of trajectories, the rectilineal motion of shot, and the calculation of tables. He explains the methods of calculating trajectories adopted by Euler, Bashforth, Niven, and Siacci. Numerous examples are given to illustrate and explain these methods, and examples taken from Bashforth's treatise are worked out by approximate and other methods.

The work concludes with three ballistic tables adapted for the calculation of trajectories by Siacci's approximate method. Table I., for spherical shot, is based upon Mayevski's coefficients (1872); Table II., for elongated projectiles, is based on Bashforth's coefficients; and Table III. is said to be copied from Didion, who copied from Euler. This table is given by Otto for every minute up to 87° 0′, which is its most complete form.

OUR BOOK SHELF

Illustrations of the Indigenous Fodder Grasses of the Plains of North-Western India. (Roorkee: Nature-printed at the Thomason Civil Engineering College Press, 1886.)

THIS is an atlas of forty plates, the representations in which are most natural and life-like, the characteristic habit of each species being effectively shown. About half the plates are accompanied by diagrams of the spikelets or florets. Of the 40 selected species, 7 belong to Andropogon, 7 to Panicum, 3 to Eleusine, 3 to Eragrostis, and 2 each to Aristida, Cenchrus, and Paspalum. The 14 remaining genera, represented each by 1 species, include, amongst others, Saccharum, Setaria, Sorghum, and Sporobolus. All the species shown are extra-British, excepting *Cynodon Dactylon*, Pers. [and *Panicum Crus-Galli*, L.]. Of these grasses none perhaps is of greater current interest than *Sorghum halepense*, Pers., known amongst English-speaking peoples as "Johnson grass," respecting the drought-withstanding capacity of which very favourable reports continue to be received from Australia and from the Western United States. Mr. J. F. Duthie, under whose careful supervision the work has been published, states in a short introduction that "the increasing demand for reliable information concerning the various grasses used in this country, either as fodder or forage, has induced me to collect materials for the preparation of a work embodying all the available information on this very important subject." This admirable atlas is a contribution in the direction indicated, and the descriptive letterpress, which Mr. Duthie promises to have ready by next cold season, will be welcomed by those—and their number is rapidly increasing—who are interested in the economic study of the Gramineæ.

W. FREAM

Exercises on Mensuration. By T. W. K. Start. (London: Sampson Low and Co., 1886.)

A WRITER who invariably mis-spells "hypotenuse" speaks of squaring two numbers and "subtracting the results," and treats of the area of a triangle before the area of a rectangle, does not deserve success. Yet so unsuited for non-technical schools is the scope of most of the existing books on mensuration, that a little manual like this of 32 pp. has an excellent chance in the struggle for existence. We hope the present edition may be rapidly sold, and followed by a second edition thoroughly revised. T. M.

Lectures in the Training Schools for Kindergartners. By Elizabeth P. Peabody. (Boston: D. C. Heath and Co., 1886.)

IN these eight lectures, which have been addressed during the past nine or ten successive years to training classes for Kindergarten teachers in Boston and elsewhere, Miss Peabody explains the system of Froebel, and the principles on which it rests. The very first sentence of the first lecture shows the serious view entertained by Miss Peabody of the duties of such teachers: "Whoever proposes to become a Kindergartner according to the idea of Froebel, must at once dismiss from her mind the notion that it requires less ability and culture to educate children of three, than those of ten or fifteen years of age. It demands more."

Le Mouvement scientifique et industriel en 1885. Causeries scientifiques. Par Henry Vivarez. (Paris: Librairie Centrale des Sciences, 1886.)

THIS volume is a republication of a number of sketches on scientific subjects contributed weekly to the journal *La Gironde,* with a view to keeping the readers of that periodical *au courant* with the progress of science in its various branches. They are therefore popular, and are made as entertaining as possible. The writer has the gift, so common amongst his countrymen, of rendering the most technical and abstruse subject clear and interesting. The "Causerie" is peculiarly a French device in journalism: hitherto it has been mainly devoted to literature and the drama. M. Vivarez has applied it with much success to science. It would be absurd to speak of this as a work of science, but it certainly is a work in which the latest results of science are explained and illustrated for the million.

LETTERS TO THE EDITOR

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

British Association Sectional Procedure

As one who has attended fourteen consecutive meetings of the British Association, with seven years' experience as a Sectional Secretary, as one, moreover, who has a high opinion of the benefit these meetings may confer upon aspiring learners and isolated workers, I venture to submit a few observations on the details of the conduct of the business of the Sections—a subject, I think, of general interest and importance.

My remarks apply directly to Section A, and only touch Sections B and G incidentally. I have no means of knowing anything about the conduct of the business of other Sections. But as regards Section A every one must feel how great a burden the papers are becoming, and how impossible it seems to deal with them adequately on the present system. The papers sent in are good and interesting almost without exception—there is no fault in the quality of the papers, it is their superabundance in proportion to the time that constitutes the evil. It is disheartening to a man who has taken much care and trouble in some piece of work, and in preparing an account of it to lay before the Section in order to get advice and encouragement for further labours, to come on at the end of a long day when every one is tired—the seniors many of them absent, and to find it expedient to abstract even his abstract, and give a hasty and barely intelligible account of what he has done: the next paper being hurried on without any adequate discussion in order to try and get through the list. I speak with the greater freedom because I have no personal grievance whatever: what I say merely represents a feeling which is certainly prevalent. Moreover, I by no means imply that any one is to blame. The effective conduct of the business of a Section in which titles of papers are liable to be handed in at the last moment is a most difficult matter, and one can only grow wise by experience.

This year the experiment has been tried of sitting on only four complete days, and of putting 35 papers down for one of them in order to avoid a Wednesday sitting if possible. My impression of the general feeling is that this has been a failure, and has resulted in a dull meeting. There are several objections to not sitting on a Saturday—not the least of which is that the break between Friday evening and Monday morning is rather a long one, and the temptation to go away is strong.

In the days when I received the traditions of the Secretaryship from Mr. J. W. L. Glaisher, a Saturday sitting was the universal rule, and it was devoted to pure mathematics. At Bradford this pure mathematical day was a most memorable and brilliant one. In those days, moreover, joint sittings with other Sections were unheard of. Electricity was then almost unknown to Section G, and the border region between physics and chemistry was less active. Nevertheless the press of papers was even at that time considerable, and a long Wednesday sitting was a frequent occurrence.

At the present time joint sittings, or semi-joint sittings, with B and G, and even with C and D, are liable to have to be provided for; and these joint sittings and interdiscussions are surely likely to be among the most fruitful and instructive periods of the whole meeting, and everything should be done to encourage them. But if time is to be found for any such discussion or joint meeting, and if at the same time the papers accepted are to be adequately treated, so as really to encourage, and not discourage, research, then I may take it as evident that it is quite hopeless to attempt to avoid sitting on both Saturday and Wednesday. Saturday is in many respects a favourable day for a sitting of A, for so many of the other Sections are then free that a good audience is frequently obtained, and opportunity for a junction of Sections is afforded. It is true that the innovation of Saturday excursions is supposed to militate against this arrangement; but Saturday excursions should not begin till middle day; moreover, if excursions are to interfere with scientific business, there ought to be no question as to which should give way.

Assuming this granted, I proceed to indicate a plan for the classification of papers so as to get a convenient list on each day, and to endow each day with a character of its own. This is an old practice, but it seems in some danger of being discarded, and it is a most useful one. Let us consider the days in order.

On Thursday there are, of course, the Presidents' addresses; not only the address in A, but also those in B and G, which are likely to draw off a considerable number of physicists. Indeed, these Sections considerately postpone their commencement till 12 o'clock, for this most desirable interchange of members. Those least affected by either of these Sections are, perhaps, the astronomers; and therefore it is convenient to fill up the rest of Thursday with papers on astronomy, tides, terrestrial magnetism, and with reports. The day thus acquires a dignified and substantial character.

Friday is a day to be devoted to pure physics, *i.e.* to papers interesting to theoretical physicists as distinguished from those concerned with celestial or terrestrial applications. The day is suitable for mathematico-physical papers, for reports on theories of light and electricity, and such like.

On Saturday the pure mathematicians should take their innings as of old: they should be the main Section for that day, and should not consent to be shunted off into some small and unknown room. The rest of the Section may either meet as a sub-section to clear off a residue of papers on general or applied physics, if any were left over from Thursday; or, if opportunity offers, it may hold a conjoint meeting and discussion with some other Section, such as B or D in that Section's room.

Monday is a day devoted to meteorology; and the growing importance of this branch claims that it should have the time fairly to itself, and not be swamped by a multitude of other papers crowded into it from other days. But inasmuch as a number of members take only a general interest in meteorology they are set partially free for attendance at other Sections, and accordingly it is becoming customary for Section G to take electrical and other communications of a physical interest on this day, and for Section B to read its papers on physical chemistry.

Tuesday is another day for pure physics, like Friday; but inasmuch as the physical aspect of chemistry is manifestly growing in importance, it is probably feasible to take papers having a more chemical bearing, as well as all those which were omitted from Friday's list. Section B would doubtless be able to take its technical papers of less general interest on this day, as it did at the late meeting.

Finally, Wednesday is a most useful day, not only for clearing up arrears, but for a class of papers often very interesting, and yet such as should not be allowed to interfere with the more serious business of the meeting at times when the *dii majores* are likely to be present in force. These are papers on minor and semi-technical points—new batteries for instance, telegraphic and observatory details, rheostats, commutators, and all manner of things, not by any means unimportant, but yet involving no serious difficulty or novelty of principle. Some of these might be taken in the sub-section on Saturday. If, by reason of discussion on other days, there are arrears of work to be dealt with, then a sub-section to deal with them may be appointed for Wednesday. Splitting of Sections is undesirable (though it is much better than destroying the whole object of the meeting by undue haste), but if it has to be done, Saturday and Wednesday are the days for doing it; partly because the work to be accomplished is by that time known, partly because few other Sections are then meeting; but mainly because the important days of general interest, Tuesday and Friday, are thus left uninterfered with, and with their interest undissipated; while on Monday, when the interest is more special, and to a less extent on Thursday also, many members may be expected to wish to attend B or G, and an A sub-section in addition is quite undesirable. The possibility of meeting at 10 on Saturday and Wednesday is a feature which enables a good deal of work to be got through, before excursions on the one day and committee-meetings on the other put an end to the sitting. Let me summarise these suggestions.

Thursday.—President's address in A. Reports and papers on astronomy and earth physics. At 12 o'clock Presidents' addresses in B and G.

Friday.—Reports and papers on pure and more mathematical physics.

Saturday.—Reports and papers in pure mathematics. Also possible joint sitting with some other Section as arranged; or sub-section for minor experimental details.

Monday.—Reports and papers on meteorology and observational physics. Physical chemistry in B. Electricity in G.

Tuesday.—Reports and papers on pure and more chemical physics. Technical chemistry in B.

Wednesday.—Arrears and papers on minor or semi-technical experimental details. Simultaneous sub-section, if necessary, for clearing off arrears without haste.

It may be felt that this means a hard week's work. Well, it does. Attendance at these meetings, if attentive, is no child's play. But if any diminution is necessary, I submit that it is better to shorten each day's sitting than to lessen the number of days. One is fresh enough at 10, when the committee work begins, but pretty tired and hungry at 3. If interest dwindles, and papers begin to hurry themselves off without discussion, or to drone themselves dismally through, it is far better for the Section to rise at 2, instead of constraining itself to continue the process till the allotted hour. On the other hand, if interesting discussions arise, and attendance is good, it is very well to be able to continue the sitting till 3 or even longer. Though, indeed, Thursday is the only day on which a sitting may happily be continued beyond 3 without being disturbed by a committee meeting.

I have now said my say. I offer no apology for treating the subject, because my single aim in doing so has been to endeavour to do something to promote the usefulness and success of these meetings. OLIVER LODGE

University College, Liverpool, September 13

The Geological Age of the North Atlantic Ocean

WHILE the interest attaching to Sir William Dawson's Presidential address at Birmingham is still fresh, I wish to be allowed to offer a few observations on that part of it which deals with the geological age of the North Atlantic Ocean. The President in referring to those writers who, like Mr. Crosby in America, Mr. Mellard Reade and myself in Britain, maintain that the North Atlantic and the American continent have in the main changed places in Palæozoic times, makes the following statement. Admitting the correctness of the facts as to the swelling out of the Palæozoic sediments in the direction of the Atlantic seaboard, he endeavours to account for these very striking phenomena thus: "I prefer, with Hall, to consider these belts of sediment as in the main the deposits of northern currents, and derived from Arctic land, and that, like the great banks of the American coast at the present day, which are being built up by the present Arctic current, they had little to do with any direct drainage from the adjacent shore." Now, in reading this passage it occurs to me that Sir W. Dawson must have felt he had a very questionable case when he attempted to support it by such an hypothesis. To liken the great sheets of sediment which spread themselves sometimes over half the North American continent south of the Great Lakes to the banks heaped up along the Atlantic coast is a point of analogy in which, probably, he will find few to concur. The Palæozoic sediments are certainly not banks, but sheets originally spread over the sea-bed, and distributed according to certain recognised laws of increase and decrease of thickness.

But, putting this point aside, I may be allowed to ask, How can we suppose the existence of a northern current bringing sediment from the Arctic regions, and spreading it over Eastern America, unless there was at the same time a coast-line to guide the current in taking a southerly direction; and if such a coast-line existed, must it not have lain along the eastern American shore, because the American continent itself was then submerged? If we examine a current-chart of the globe, we find that all the N.–S. oceanic currents flow along the continental shores and take their directions from them. If America and the Atlantic, south of the Arctic regions, were both oceanic in Palæozoic times, then the current would not have been southerly, but westerly or easterly, according to circumstances, certainly not flowing from north to south; therefore this explanation for the distribution of the Palæozoic strata cannot, I venture to say, bear the test of examination.

Again, the President states: "It is further obvious that the ordinary reasoning respecting the necessity of continental areas in the present ocean basins would actually oblige us to suppose that the whole of the oceans and continents had repeatedly changed places." Now, as regards the North Atlantic, this is an objection which is purely imaginary; because the evidence goes to show that it remained in the condition of a continent all through the Palæozoic ages, with, of course, ever-varying margins; and it is only so far (as a writer in the *Athenæum*, September 4, has properly pointed out) that I have argued in favour of its continental condition. But undoubtedly the arguments in favour of the interchange of ocean and continent during Palæozoic times, as applicable to North America, would be found to apply more or less strictly to other oceans and continents, owing to the wide distribution of the formations of this period over the present continental areas. Northern and Central Africa and Greenland may prove exceptions; but apart from these tracts, Palæozoic strata appear to have been distributed (prior to denudation) over by far the greater portions of the continents, and the sediments must have been derived from the adjoining continental areas, which are now covered by the waters of the ocean.

The question between the President and myself is mainly this: Did the sedimentary strata of the Palæozoic period of North America come from lands lying around the Arctic Circle, or from others occupying the position of the North Atlantic? American geologists have a favourite theory that the Arctic regions have been the originating lands, but I venture to repeat that if it be allowed as a general principle that the originating lands lay in the direction towards which the sediments thicken, and opposite to that in which the limestones are most developed, the conclusion is inevitable that the Atlantic was in the main a land-surface in Palæozoic times. All the Palæozoic formations of North America point to this conclusion, as I have on former occasions attempted to show,[1] and this, regardless of the question whether or not there was also land along the Arctic Circle. Throughout the Silurian, Devonian, and Carboniferous epochs marine limestones were in course of formation mainly over the regions west of the Mississippi, and sediments mainly east of that line and chiefly in the Appalachian region. The general direction of the swelling out of the sediment is (if I mistake not) rather south of east than north of east. Thus, the "Potsdam beds" appear to swell out towards the E.S.E.; the "Hudson beds," S.E., and S.S.E.; the "Hamilton beds" of the Devonian, towards the E. or E S.E.; and different members of the Carboniferous series swell out N.E., E., and S.E. On the whole, and as a general result, the centre from which the sediments appear to have been chiefly distributed seems to have lain around the point intersected by the parallel 30° N. lat. and the meridian of 60° W. long., except in the Carboniferous period, when the originating lands appear to have lain in the region of the first Atlantic cable, between Newfoundland and the British Isles, and which lands were probably continuous with those of the Arctic continent.

I wish, in conclusion, to take this opportunity of adding a few words in reference to the Archæan rocks. I am much disposed to concur in the view of Sir W. Dawson—that the fundamental gneissose beds of the Archæan period may have had a different origin from the metamorphic strata of succeeding periods, and that they may not have been originally sediments. This observation does not, however, apply to the schists, limestones, and quartzites which succeed them, and which sometimes include beds of gneiss, as in Scandinavia. From this point of view, the birthday of the Atlantic continent may not have dated farther back than the commencement of the Palæozoic age—represented in Britain by the Cambrian, and in America by the Potsdam, sandstone. As a continent it remained till the close of that age. To what extent it survived the terrestrial movements which closed that epoch I am not prepared to say.

Dublin, September 15 EDWARD HULL

Earthquake at Sea

CAPTAIN H. J. OLSEN, commanding the brig *Wilhelmine* of Drammen, reports that, on the 1st inst., being by dead reckoning in lat. 50° 10′ N., long. 1° 40′ W., he observed, between 3.30 and 4 p.m., three rumblings at short intervals, during which the ship was felt to tremble violently, so that both the bulwarks of the cabin and plates on the table clattered. The wind was north-west, with a gentle breeze, and the ship was on the starboard tack. H. MOHN

Det Norske Meteorologiske Institut,
Christiania, September 15

Peripatus

NATURE for July 29 (p. 288) mentions that *Peripatus* has been taken at Demerara. It may interest some of the readers of

[1] *Scient. Trans.* Roy. Dublin Soc., vol. iii. 2 ser. p. 305 (1885), and "Contributions to the Physical History of the British Isles," p. 27 *et seq.*

NATURE to know that in January 1881 I captured a single specimen of *Peripatus* in the low, damp woods at Breves, on the island of Marajó, mouth of the Amazon. The specimen is now in the entomological collections of Cornell University, Ithaca, N.Y. JOHN C. BRANNER

Bloomington, Ind., U.S.A., September 2

THE RECENT EARTHQUAKE IN GREECE

I FORWARD the inclosed copy of a report made by the master of the steamship *La Valette* in reference to the earthquake which occurred in Greece last month, in case you may not have received the report and might wish to publish it.

W. J. L. WHARTON, Hydrographer

Admiralty, September 20

Report made by the Master of the s.s. "La Valette" to the Superintendent of the Ports, Malta, furnishing certain particulars in connection with the earthquake which occurred on August 27

On the 27th inst., at 11.30 p.m., whilst in lat. 36° 18′ N. and in long. 21° 32′ E., or at a distance of 50 miles W. ½ S. from Cape Matapan, I felt, all of a sudden, a very strong shock, which made the ship tremble, especially the engines, for the space of about 11 seconds. The ship was proceeding at the rate of 10 knots an hour, and with such shaking lost her course. The engineer thought that the screw had been lost. After the shaking was over all was right again. At midnight in the direction west-north-west, in lat. 36° 17′ N., long. 21° 27′ E., I observed on our right something like a mass of thick black smoke, which, like a cone, was rising up perpendicularly from the horizon, and at intervals changing into a reddish colour. In the meanwhile a perfect calm prevailed, with heavy sea from west at intervals. At 4 a.m. of the 28th, when the ship was in lat. 36° 12′ N., and in long. 20° 43′ E., the wind commenced blowing from north-west, which made the horizon a little clear. At 10 a.m. the mate, who was on watch on the bridge, reported to me that he had observed in the sea several stripes of a dark yellowish colour about one quarter of a mile long in the direction from north to south, which looked like shallows. The sea continued always heavy from west with very little wind. As the ship had a cargo of cattle, which suffer greatly from heat, I could not lose time in measuring the depth of the aforesaid stripes; therefore I tried to avoid them. During the navigation I thought proper to take precautions, as when I was at Alexandretta my owners informed me by telegraph of the report made by Capt. Tomlinson, of the steamer *Transition*. (Signed) CAPT. L. AQUILINA

Malta, August 29, 1886

THE TOTAL SOLAR ECLIPSE OF 1886

WE suppose that if, some months ago now, when the question of sending out an Expedition to Grenada during the rainy season was first discussed, any one had prophesied that out of a party of eight seven would see the eclipse and record results, the general feeling would have been that such a view would have been too sanguine. This, however, is what has happened, and so far as the securing of observations and photographs goes the Expedition must be pronounced a success.

With regard to the total result, however, no one is yet in a position to speak with certainty, for some of the photographs taken are not yet developed, and others, though developed, have not been submitted to any examination. On this point, however, we need not lay any great stress, for such photographs, though invaluable as records, do not help yet so much as such pictures will certainly be made to do hereafter in the matter of solar theory, for the reason that they are not large enough and not detailed enough.

Has, then, solar theory been advanced by the eye observations? From the sketch of the work done which appeared in yesterday's *Times*, from the pen of a Correspondent in Grenada, and which we reproduce, we think it has certainly. Prof. Tacchini's observation that the prominences seen most prominently during the eclipse were not the prominences seen by the ordinary method, and that the latter only reveals part of a very complicated phenomenon, is valuable in itself, but taken in connection with the fact that the eclipse prominences and the parts of the prominences not seen by the ordinary method are probably downrushes, wholly or partially, it is difficult to overrate its importance. These eclipse prominences, which Prof. Tacchini calls "white" prominences, are high and filamentous, and that distinguished observer, we know, does not hesitate to express his belief that the "comet" seen in the eclipse of 1882 was really one of them. If this be so, then the meteoric downpours of consolidating and consolidated materials are already *en évidence* with a vengeance, and these are the parts of the solar economy we want most to lay hold of just now.

That part of the *Times* Correspondent's letter which refers to the results obtained runs as follows:—

"The Green Island party was the only one doomed to disappointment. At Carriacou, Boulogne, Hog (or Fantôme) Island, and Prickly Point the eclipse was seen and results secured, although at these places even it was touch and go, the sky being cloudy everywhere. Carriacou was most highly favoured. During the totality the sky was cloudless, though the sun was covered one minute after the rim re-appeared. At Fantôme Island the last 40 seconds, and at Prickly Point the first 50 seconds, were lost. At Boulogne the clouds were still more persistent, and cut off 70 seconds of the totality, although Mr. Turner secured some observations during the four minutes before and the five minutes after. The presence of cloud during totality is a more serious matter than it might appear at first sight, for not only is the time reduced during which precious facts may be recorded, but pre-arranged programmes are interfered with, and it may be necessary to change them in order to meet the altered conditions. This requires a rapid and wise decision.

"Before I attempt to give any summary of the general results obtained, it may be remarked that the kinds of work attempted as a rule by eclipse expeditions are four in number, and are very distinct both in their methods and results from each other. We have first of all new facts, or new views of facts, which experience shows us are always obtained at such times, though they are not sought for as such. Next comes the testing of views which have been put forward to explain and harmonise the results previously obtained, and this part of the attack becomes very important when there are rival hypotheses in the field, the superiority of one of which can be established by a few critical observations. The third kind of work is the testing of the new methods of obtaining facts, the introduction of new instruments, or of new or improved ways of using old ones. Only in this way can a complete and perfect system of eclipse observation be built up. Finally we have the application of the ordinary methods of obtaining records, which for the most part are photographic. Astronomers not only want to study the phenomena of each eclipse to get at the physical and chemical structure and nature of the sun's atmosphere, but they want to note the changes from eclipse to eclipse, in order to see which phenomena are liable to variation, and the extent and period of such variation if it exists.

"Now in the eclipse observations secured in Grenada and Carriacou a distinct advance has been made along all the four lines to which reference has been made. New

facts have been acquired, old views have been satisfactorily tested, new instrumental methods have been studied, and records of the general phenomena have been secured. I will as briefly as possible go over each of these points in turn.

"First as to the new facts. For these we have to refer to the work of Prof. Tacchini at Boulogne. No one was more competent than he to note the prominences and other appearances visible during the eclipse. This he did with a 6-inch, and so soon as the clouds permitted after the eclipse he observed the spectrum of the prominences by the ordinary method. He found that the prominences seen under these two different conditions and by means of such different methods were not the same. He also noted that the prominences seen during the eclipse itself had the same characters as the so-called 'white' prominences which he observed in 1883 at the Caroline Islands. These appear whiter and dimmer as the distance from the photosphere increases. These observations have been very closely examined by Prof. Tacchini and Mr. Lockyer, with the result that both these solar observers are now prepared to ascribe these new phenomena to the descent of relatively cool material.

"It is difficult to over-estimate the importance of this result from the point of view of solar theory. The determination of the direction of the currents in the solar atmosphere is indeed so important that it was included in the programme of the observations to be made by Mr. Turner with his 4-inch finder, but no certain results were secured by this means, as the structure of the corona was apparently unusually complicated. In the spectroscope, however, one long streamer was observed to be much brighter near the limb. This is not absolutely conclusive evidence, but it has its value.

"To return, however, to Prof. Tacchini's other observations. He found that the prominences which were visible both during totality and by the ordinary method presented very different appearances, so that we are driven to the conclusion that by the latter we only see part of the phenomena. This entirely accords with Mr. Lockyer's recently published views, in which it is suggested that the metallic prominences seen near spots are really mixed up and down rushes, with probably an excess of the cooler descending material. Thus, for instance, the metallic prominences observed by the ordinary method after the eclipse were found to be only the central portions of those observed during totality, the part visible only during totality forming a whitish fringe round the more incandescent centre. Another very important observation was made. The 'flash' of bright lines, attributed by Prof. Young to the existence of a thin stratum which was supposed to contain all the vapours the absorption of which is registered by the Fraunhofer lines, was found to be due solely to the great reduction in the intensity of the light reflected by the earth's atmosphere allowing the spectrum of the higher regions to be seen the moment the lowest stratum of the corona was covered by the moon. This is carrying the unveiling of the spectral effects by the increasing darkness recorded in the Egyptian eclipse to its furthest limit, and it harmonises all the observations of this kind made since the eclipse of 1870.

"So much in the way of new facts and new ideas. We next come to the second kind of work, the testing of old ones. In this connection we have to refer to Mr. Turner's work at Boulogne and Mr. Perry's at Carriacou. Mr. Lockyer, before the eclipse of 1882, had been driven by a long series of experiments and observations to conclude that the lower part of the atmosphere was composed of successive strata giving different spectra, and that the sole cause of the difference was temperature. A test was possible during an eclipse, for then these lines of any substance seen to brighten when a higher temperature is employed in the laboratory should be seen shortest and brightest. The test was perfectly sharp and definite. It was applied during the eclipse of 1882, and the lines appeared as predicted.

"So far, then, the hypothesis which had enabled a prediction to be made which was subsequently verified was worthy of confidence. But this was a reason for repeating the observations to put the hypothesis on a wider basis. Mr. Turner did this, and found that the facts observed this year were the same as those recorded in 1882. It remains now for those who oppose Mr. Lockyer's views to give a more simple and sufficient explanation of those facts than he has done. Mr. Perry was to have extended the test further, but he failed to make the critical observation, as a large number of lines were seen, and those only for a short time, for the clouds came up directly after totality.

"Capt. Darwin was charged with a test of a different order. It was stated, after the eclipse of 1871, that the light of the corona was in all probability strongly photographic; and in 1875 the evidence in this direction was greatly strengthened, and some attempts were made to utilise this quality to obtain photographs of the corona without an eclipse. The efforts failed. More recently Mr. Huggins has tried the same methods with great precautions, and he has obtained appearances on his plates which resembled the corona, so that some thought that success had been achieved. The natural thing to do was to test the method during the progress of the eclipse to see if the appearances in question, due to atmospheric glare according to some, to the corona according to others, really resembled the corona when revealed by totality. Capt. Darwin's work seems to leave no doubt that the effect is due to glare only, and that the corona has nothing to do with it.

"Next as to new methods of attack. This year the only new method applied has been a change of the photographic manipulator, with a view of obtaining a much larger number of photographs and increasing the size of the images at the same time, by using larger lenses of longer focus and secondary magnifiers. Along this line success has not been complete, because the photographs have not been actually taken, as this new work was undertaken by Mr. Lockyer and his party at Green Island, and was clouded out. In spite, however, of this want of photographs, Mr. Lockyer will not hear of want of success. He holds that the problem has been solved.

"I have given an account of the work at Green Island, including the results of the rehearsals, and your readers will have been able in a large measure to form an opinion of their own. The improvement consists essentially in using four plates in one slide. The difficulty always has been in getting the slide in and out of position, so that the more plates we can work in one slide the more the difficulty and consequent loss of time are evaded. Another advantage lies in the use of a secondary magnifier, as by this means not only is the photographic image of the sun enlarged, but a system of cross wires can be introduced which permits of a perfect orientation of the picture obtained—that is, the exact east and west points on the circumference can be determined with the utmost precision, and from this the position of the various phenomena with regard to the sun's equator and poles. It can be easily imagined that on this point there must be no uncertain sound.

"We next come to the photographic record obtained by old methods—that is, methods dating in the case of photography of the corona from 1852, and in the case of spectrum photography from 1875. About twenty photographs of the corona have been obtained in all, and five photographs of the chromosphere and lower regions of the corona. Mr. Maunder obtained seven of the corona, and could have obtained more, at Carriacou. Captain Darwin obtained six, and Dr. Schuster, we believe, five, at Prickly Point. Of the photographs seven spectra, two with the

solar spectrum on the same plate—the only ones worth anything, have also been secured by Mr. Maunder. But we must not build too much on this, for, as I have said before, these photographs have not yet been developed; but if only one good one has been received, the laboratory work it should set going will take at least one or two years before the teachings of the precious record are exhausted. The so-called 'measurement' of such photographs is worth next to nothing.

"Among the records obtained on this occasion must be classed the disk observations, now for the first time included in the ordinary routine of eclipse work. The point of a disk observation is that an observer is by its aid able to observe the outlying solar appendages under the best conditions, so far as the sensitiveness of the eye is concerned. For ten minutes before totality the observer is blindfolded, and at the moment of the totality he is led to a small aperture through which, the bandage over his eyes having been removed, he sees a black disk some 40 feet away, which shuts off the moon and the brighter interior portion of the solar atmosphere. The eye, therefore, being thus shielded, is in the best position to pick up faint streamers extending beyond the borders of the disk, and to note their positions and extension. Streamers were thus noted at Grenada, extending far beyond the limits seen in the ordinary way, but the air was so saturated with aqueous vapour and incipient cloud, even where substantial clouds did not make their appearance, that the failure of any of the observers to see the equatorial extension observed by Prof. Newcomb in the clear sky of Wyoming, at an elevation of 7000 feet, in 1878, by no means proves that the extension was not there. The question of the continual existence of an extension of matter of some sort or other in the plane of the sun's equator must be held to be still *sub judice*.

"Capt. Archer at Fantôme Island, and Capt. Maling at Prickly Point, made disk observations fairly accordant. The former had greatly improved the disk provided him by surrounding it with concentric rings of wire, so that distances from the centre could be measured with the greatest accuracy.

"The records obtained by Prof. Thorpe regarding the intensity of the light of the corona were sufficient in number to suggest that when they are reduced a value will be obtained to be placed side by side for purposes of comparison with those previously obtained in 1870 and 1878. In this connection it may be remarked that the darkness of an eclipse must not be taken as a measure of the dimness of the corona, for, if the totality be longer, more of the brighter portion of the solar atmosphere will be covered. This was certainly the darkest eclipse seen since eclipse expeditions have been in vogue. This shows the importance of Prof. Thorpe's work, for if successful it will give us the luminous intensity per unit of surface of different regions of the solar atmosphere, as well as the intensity of the total light emitted.

"The preceding sketch of the results obtained has of necessity been of the most general character. Not till all the observations are published in detail, as they doubtless will be at no very distant date by the Royal Society, and not till they have been discussed by those competent to discuss them, can a final verdict as to their value be given. We have of set purpose dealt only with the conclusions which lie on the surface."

NOTES

THE death of Alessandro Dorna, Director of the Astronomical Observatory of Turin, took place on August 19 last, at the age of sixty-one years.

THE annual Congress of the Sanitary Institute of Great Britain commenced on Tuesday in York. Sir T. Spencer Wells, the President, commenced his inaugural address by expressing the hesitancy with which he accepted the position of President of the Congress, a hesitancy induced by the knowledge that he could not presume to appear before a body of sanitary experts as an instructor. Having referred to questions which had been dealt with in regard to sanitary science by his predecessors in the Presidential chair, he observed that it now remained to be considered how sanitary improvements might be carried still further by the co-operation of investigators, legislators, and administrators. As to the work of investigation, it had hitherto for the most part been personal, and the waste of labour had been enormous. The Institute must develop into something grander and more powerful. The Colleges of Physicians and Surgeons had done much, but it was rather for individual than collective good. Why should we not have a College of Health? The President then reviewed the work which those whom he called the "advanced guard of sanitary science" had accomplished, in lessening the death-rates of our population, and in benefiting the public health by prolonging life. Much of this he attributed to the coincident progress made in the science and art of medicine and surgery. He claimed for the medical profession a considerable share in the gain to the State of increasing numbers of more healthy subjects. We could not be far wrong if we put the average duration of human life in Great Britain half a century ago at about thirty years; now, according to the healthy life table, it was forty-nine years. Formerly it was calculated that a twenty-third part of the population was constantly sick, and the products of all that labour for the time necessarily withdrawn. A great deal of this sickness had been altogether prevented, and the duration of that which comes in spite of sanitation was lessened. He then dealt with the progress which had been made, since the Sanitary Institute had come into existence, in the moral and physical condition of our population. Dealing then with the various subjects to which the Institute had given attention, he divided them into five groups: (1) those relating to the training and health of the population; (2) to their social comfort and well-being; (3) to the prevention of disease; (4) to the care of the sick; and, lastly, those relating to the disposal of human refuse and remains. As to teaching the public on sanitary matters, it could never be done without elaborate organisation and legislative authority.

ONE of the tasks undertaken by the authorities of the British Museum since printing has taken the place of handwriting in the Catalogue is the publication of certain important sections of the Catalogue in separate parts. Thus the entries under America, Cicero, Luther, London, and many others have already appeared. The last of these is one of special scientific interest: it is a reprint of that part of the Catalogue which is classified under the head Academies. The definition of academies for the purpose is "Learned and Scientific Societies." The entries fill five parts, making a thick folio volume of about one thousand pages. In the great written Catalogue, which is well known to all readers, twenty-eight volumes were given to this one subject. The headings have been thoroughly revised throughout, and the names of a number of societies have been expunged, to be placed under more appropriate headings. Thus, agricultural societies, schools, political clubs, &c., which had crept into the Catalogue by degrees in course of time, have all been omitted. As it is, the total number of entries is about 32,000. "London" is the longest sub-heading; it fills nearly 200 pages, with about 6500 entries. Paris, St. Petersburg, and Berlin have about 3000 entries each; Vienna and Amsterdam about 1000. Towns are used for sub-headings, and under these are arranged alphabetically the names of the societies issuing the publications. The old sub-headings of countries have been abolished. Formerly the sub-headings would read thus:—

"Academies, &c.—Great Britain and Ireland,—London, Royal Society." The towns are now arranged alphabetically, regardless of countries. Only completed series are fully entered; works in progress are, according to the rule of the Museum, catalogued with the date of the first volume, and the words "in progress." The work covers the greater part of the scientific literature of the world; when the Catalogue of "periodical publications" is finished, there will be little relating to science which cannot be found under appropriate heads in one or the other. It seems like looking the gift-horse in the mouth, but we cannot refrain from observing that the value of these five volumes would be enormously increased if some approximation to a subject index could be added to them. It would be a simple task to have headings Chemistry, Microscopy, Geology, &c., under which were given the names of the towns where societies on these subjects are to be found. The student would then have before him at a glance the names of all the societies on the globe working at any particular subject. Instances will present themselves to every student in which the first name of a society, and that by which it has to be sought in the Catalogue, does not always indicate the sphere of work of the society. The price of the Catalogue unbound is, it should be added, a sovereign.

THE small launch *Volta*, which is propelled by the electric current, in a method invented by Messrs. Stephens and Co., of Millwall, left Dover on Monday morning last week on her voyage across the Channel. The hull of the *Volta* is 37 feet long and nearly 7 feet beam, built of galvanised steel plates. She has a very light appearance in the water. Her bow is about 2 feet above the water-line, and from this point down towards the stern she gradually reduces the depth of her gunwale. Her deck is nearly or quite on a level with the water. Below the deck, which is securely fastened down, are placed the electric accumulators, all coupled together with the coils. They are little square boxes about 6 by 12 inches, and are wedged in closely together so as to prevent shifting, and to fill the whole of the space below the deck. The propelling power consists of sixty-one accumulators, and a pair of Reckenzaun electromotors, also placed beneath the floor, so that the whole of the boat is available for passenger accommodation. The motive-power is under complete control, and the speed can be regulated to whatever rate is required. The speed of the launch is regulated by a main switch, and there are special switches for going astern, the whole of the apparatus being easily managed by one man. The power of the motors may be varied at will from 4 horse-power to 12 horse-power, whilst the screw-propeller, which is coupled direct to the motor-shaft, makes from 600 to 1000 revolutions per minute, according to the position of the switch handle. The *Volta* returned to Dover shortly before 8 o'clock, having completed a voyage which is regarded as a great scientific success. When the boat arrived at Calais it was found that the amount of electricity remaining in the accumulators warranted the return journey being attempted. When the voyage was completed, the current from the accumulators was still powerful, notwithstanding that during the last half-hour of the journey the launch had been driven at the rate of 14 miles an hour, and rushed through the water at such a rate as nearly to throw it over her bow. The total distance traversed was about 50 miles. During the voyage the speed was varied at will by means of the switch. The experiment is regarded by all those on board as a success far in advance of anything they expected. An incident occurred on the passage which illustrates the noiselessness of the little vessel. About mid-Channel the pilot observed a sea-gull floating asleep on the water. The boat was steered close to the bird, which was caught by the neck by one of those on board, and brought alive to Dover.

INTELLIGENCE has been received from Lieut. Schwatka, who was sent to Alaska in command of an exploring Expedition by the proprietors of the *New York Times*. On the way to Mount St. Elias, which dominates the range to which the same name has been given, the party crossed a river, the existence of which had been hitherto unknown. At a distance of eight miles from the mouth it is a mile in width, and its current flows at the rate of ten miles an hour. This is thought to be the largest river that enters the Pacific Ocean, and the glacial mud it brings down with it discolours the waters of Icy Bay for some miles out to sea. The river has been named Jones River, after Mr. George Jones, of New York, one of the promoters of the Expedition. To the east the explores saw a glacier twenty miles wide, which extended for fifty miles along the base of the St. Elias Alps. Assuming the land beneath it to be flat, the thickness of this glacier is about 1000 feet. It was named after Prof. Agassiz. Another glacier, to the westward, was named after Prof. Guyot. After three days' marching, Lieut. Schwatka and his party came upon a third glacier, which they named in honour of Prof. Tyndall. From this point they resolved to make a final dash as far as they could go into the heart of this grand but desolate icy region. At the end of twenty hours' labour they came in sight of the south side of the great mountain to which belongs the icy girdle along which they had been travelling. They saw before them glaciers rising, sometimes perpendicularly, to heights varying from 300 to 3000 feet. The Tyndall glacier, comparatively safe so far, was safe no longer. Enormous crevasses, some as much as 30 feet across, now became frequent; and the bands of ice between them were so narrow, that, in places, the explorers appeared to themselves to be walking on a bridge like that of a house roof, with a chasm hundreds of feet deep on each side. These and other difficulties, such as are familiar to Alpine climbers, had been surmounted until a height of 7200 feet above the level of the sea had been attained. As nearly the entire journey was above the snow-level, this ranks among the best climbs on record. The Lieutenant telegraphs that he hopes, by renewing his attempts upon the mountain on its northern and eastern sides, to make further contributions to geographical science, and perhaps to ascend the mountain to a greater height; but the probability is that Mount St. Elias will long remain an unscaled peak. Mr. Seton Karr states that the whole region is vastly superior to any other mountainous district with which he is acquainted. One incident of the journey was the discovery of three peaks, ranging from 8000 feet to 12,000 feet in height, which were severally named after President Cleveland, Mr. Secretary Whitney, and Capt. Nicholls.

LAST autumn a few science classes were started as a preliminary experiment in rooms belonging to the Royal Victoria Hall, at the nominal fee of 1*s*. on first entrance and 1*s*. 6*d*. per class for the session. The success achieved has encouraged the promoters to extend the scheme, and this year it is intended to hold classes in mathematics, chemistry, animal physiology, drawing, arithmetic, geometry, electricity, political economy, and English literature. Some of these classes will be in connection with South Kensington. Last year they were welcomed in the most enthusiastic way by the comparatively small number who knew of their existence; no pains were taken to advertise them, as it seemed likely the numbers would exceed the available accommodation. This has now been improved, and it is hoped that a very useful branch has been added to the work at the Hall. The entertainments, concerts, and lectures which go on in the large hall are in no way interfered with thereby; in fact the lectures gain by the existence of systematic instruction to which they lead up. Those at present announced are: October 5, Mr. W. L. Carpenter, on "What may be done with a New Lantern"; October 12, Dr. W. D. Halliburton, on "The Germs of Disease"; October 19, Prof. Judd, on "A Piece of Pumice-Stone."

THE Canadian salmon on view in the Canadian Section of the Colonial and Indian Exhibition which were hatched out last April in the building are thriving well.

THE Indian fish lately imported into the Aquarium of the Colonial and Indian Exhibition from Calcutta seem thoroughly at home in their artificial existence. There are two species on view, viz., the *Sacchobranchus fossilis*, or scorpion fish, and the *Ophiocephalus striatus*, or walking fish. A large consignment of German carp has just arrived, together with some Chinese goldfish and specimens of *Siluris glanis*.

THE first field-meeting of the County of Middlesex Natural History and Science Society was held on Saturday, the 18th inst., at Hampstead and Highgate. Between 60 and 70 members assembled at Hampstead Heath Station at 2.30 p.m., and were conducted thence by the Rev. F. A. Walker, D.D., and Mr. Clement Reid, F.G.S. Passing along the top of the Vale of Health to "Jack Straw's Castle," the party proceeded along the northern side of the Heath and reached "The Spaniards" about 4.30. At different points on the route the geology and physical features of the district were explained by Mr. Reid. At "The Spaniards" the party were unexpectedly met by Mr. Goodwin, of Highgate, who had obtained the kind permission of Lord Mansfield for the members to walk through the Park. Mr. Goodwin conducted the microscopical section to the ponds, where they were richly rewarded. Leaving the Park, the party proceeded to Highgate Schools, where they were received by Dr. McDonall, the head master, entertained at tea by the honorary secretary, Mr. Klein, and they afterwards inspected the collections of insects, mostly collected and arranged by Dr. Walker. At 7 o'clock the members assembled in the theatre of the Highgate Institute, where, after some short notes by Mr. Lloyd, the honorary secretary of the Institute, on "Highgate and Highgate Worthies," Mr. Mattieu Williams read a short paper upon "Some Peculiarities of London Atmosphere," which was followed by a discussion, in which Messrs. W. L. Carpenter, R. Hammond, and others took part. The Rev. Dr. Walker then made some interesting remarks on the different orders of insects represented in the collections of the Highgate Schools.

Science reports that Captain Dutton, of the United States Geological Survey, has recently been engaged in studying Crater Lake in Oregon, which he has found to be probably the deepest body of fresh water in the country. Boats were transported over a hundred miles of mountain road from Ashland, and had to be lowered 900 feet to the water. The steepness of the wall of the lake was very great. The depths ranged from 853 to 1996 feet, the average being about 1490 feet. The descent to the lake is partly over talus, covered with snow above, and rocky broken ledges lower down.

THE works for deepening the Seine to a depth of 3 metres have been finished. The river can now be navigated by vessels of about 1000 tons burthen, which are supplied with movable masts and chimneys for the bridges.

WE have received the report of the Otago Acclimatisation Society for the past year. The operations of the Society have been almost entirely confined to pisciculture, and apparently must be so for some years owing to the spread of poisoned grain over the country, and to the increase of the natural enemies of the rabbit, which are also the natural enemies of birds. But in pisciculture much has been done, and much more remains to be done, for the salmon and the herring are not yet numbered amongst New Zealand fishes. An experiment, which has so far been successful, for the introduction of the *Salmo salar* has been made; similarly in the cases of Loch Leven trout, *Salmo fontinalis*, and brown trout. Brown trout have been acclimatised with such success, that the Society is in a position to supply an almost unlimited demand for ova, as well as to provide liberally for the requirements of New Zealand streams. The late secretary, Mr. Arthur, had begun the collection of a series of data from which he hoped to gain some information respecting the sea-fish of New Zealand, and ultimately to arrive at something definite in regard to the nature and habits of some of the most important of them. The collection and tabulation of these returns and the important investigations of Mr. Arthur are being continued by Mr. Thomson. It is perhaps scarcely necessary to add that Sir James Maitland has seconded the efforts of the Society in acclimatising *Salmonidæ* in every possible way. The only wonder is that important public work of this nature should be left wholly to private endeavour.

A "transportable electric lighthouse" has been lately invented by M. Beduwe, a builder in Liége. The idea is, to furnish the light in any place on short notice; and it is thought the apparatus might prove useful in public works, cases of accident, gatherings in public places, *fêtes*, &c. The constituent parts are (1) a telescopic system of copper tubes bearing the light; (2) a three-cylinder steam-engine to drive either a Gramme machine, or a suction and force pump; (3) a vertical boiler on the tubular system; and (4) a reservoir for water. The whole is mounted on a four-wheeled carriage. The light is raised by hydraulic force. Further details may be found in *Le Génie Civil* of September 4.

THE first number of a monthly scientific journal made its appearance at Rio de Janeiro on July 25 in connection with the Philotechnic Institute of that city. It bears the title of *Revista Philotechnica*, and takes the place of the recently defunct *Revista Polytechnica*. Its object will be the practical and experimental study of the sciences, and of their application especially to the development of the arts and industries in Brazil. The first number contains papers on practical astronomy, by F. Behring; on building materials, by F. de Sá; and on practical chemistry, by Ad. Uchõa, chief editor.

A NEW YORK telegram states that several detonations and tremors occurred at Summerville between Saturday night and Monday night, and three shocks of earthquake, two of which were accompanied by detonations, were also felt there early on Tuesday morning. At Charleston three shocks of earthquake occurred on Monday night, one of which, at about daybreak, shook the houses to such an extent that many of the occupants ran terrified into the streets. One of the shocks was accompanied by detonations.

THE additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey (*Cercopithecus cynosurus* ♀) from West Africa, presented by the Rev. H. R. Moolenaar; a Black-backed Jackal (*Canis mesomelas*) from West Africa, an Algerian Tortoise (*Testudo mauritanica*) from North Africa, presented by Mr. A. T. Marsh; two Elegant Galidias (*Galidia elegans*) from Madagascar, presented by Mr. Burt. C. Muller; two Black Rats (*Mus rattus*) from Sark, Channel Islands, presented by Mr. W. F. Collings; a Bateleur Eagle (*Helotarsus ecaudatus*) from Lamoo, East Africa, presented by Dr. W. Somerville; a Wild Duck (*Anas boschas*), European, presented by Mr. K. Lawson; a Barn Owl (*Strix flammea*), European, presented by Mrs. E. Holloway; a Common Marmoset (*Hapale jacchus*), two Black-eared Marmosets (*Hapale penicillata*) from South-East Brazil, a Common Otter (*Lutra vulgaris*), British, two Ariel Toucans (*Ramphastos ariel*) from Brazil, deposited; a Common Crowned Pigeon (*Goura coronata*), two Auriculated Doves (*Zenaida auriculata*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN
